North American Mound Builders: Hopewell, Natchez, Cahokia

James A. Brown
Anthropology, Northwestern University, Evanston, IL, USA

Introduction

In the minds of most Americans of the nineteenth century, the native inhabitants encountered in the eastern United States were not the builders of the earthen monuments scattered across the landscape. Native Americans found living among them north of the Ohio River professed no knowledge of their builders. The mounds must have been constructed in the distant past because centuries-old trees were found growing on them. The two findings coalesced into the belief that the mounds were remains of a lost race that derived from Mexico where mound building had a long-recognized history. It was not until archaeological investigation had conclusively determined that Native Americans were indeed descendants of the Mound Builders that the invention of a lost race was disposed of. These same investigations demonstrated an antiquity that rivals that of their presumed source south of the United States. Mound building can be traced to back to 4000 BCE (Milner 2004). As a consequence, the central reason for seeking external influence ceased to be relevant. But other considerations remain. Beliefs and practices known ethnohistorically as well as archaeological evidences are reminders that Mesoamerican culture is not entirely divorced from the history of the mound builders. The question remains – were Mesoamerican innovations so important that they were responsible for creating structural changes in the long-term history of the mound builders? Or did they only color that history? A tension between these positions poses an appeal to exogenous forces on the one hand as against a history that is essentially self-contained. The final assessment is likely to be a more measured perspective as new research sheds light on old assumptions. The quest for answers continues to stoke many debates including the role of Mesoamerica.

Definition

Presently, the ethnic connections between the precontact builders of mounds and the post-contact Native Americans are firmly established. Notwithstanding this connection, no other overall designation has arisen to replace the term, mound builders, despite its origin in a racial mythology about the precontact inhabitants of the eastern United States. It does have usefulness as applying to a major historical chapter in the history of Native Americans. In the first place no single group of people is descended from these ancient peoples. Diverse language groups appear

to have participated in major mound-building programs. The major language groups are the Caddoan, Iroquoian, Muskogean, and Siouan. However, it is probably no accident that their descendants and cultural representatives happen to have been singled out by congress in the nineteenth century as deserving a distinct citizenry status as the Five Civilized Tribes (Fogelson 2004; Townsend and Sharp 2004). Although these tribes dominate the list of descendants, many smaller tribes that had historical connections to the Mound Builders lost their separate identity by incorporation into larger tribes, such as the Creeks. Among them are the Natchez of the state of Mississippi, who were a notable example of a once famous mound-building tribe that joined the Creek Confederacy out of necessity.

In many respects, our perspective to the precontact history of the East has been framed by a natural historical approach to the past. Tracking the historical ecology through time has been enormously successful in explaining economic and social developments (Smith 1993, 1995). Improvement in the productivity of natural environments following the Ice Age has been an important factor in increasing the resource base for humans and extending the duration of sedentary settlement. Against the background of this process, plants became domesticated from local species, although the fact that some of these species were the same or potentially the same as plants in Mesoamerica has led to a reawakening of old debates (Smith 1995). A critical area of debate has been over the role maize cultivation had in supporting cultural complexity and major monument construction. That debate has been settled by placing monuments well before the introduction of maize around 1 CE. Even in the centuries that immediately followed its introduction, archaeological discovery has shown that maize was a minor dietary item until about 1000 BE and did not dominate foodways until 1200 BE. As important as the development of maize consumption was in fueling Mississippian Period societies, it cannot be cited as a factor earlier in time.

The place of domesticated plants in mound builder history continues to be a critical issue, although the debate over the source of the principle starch grain (*Zea mays*) has been settled by establishing the Southwest as the immediate source, not directly with Mesoamerica (Smith 1993, 1995). However, the possibility exists that various varieties of this and other domesticates were introduced more directly.

The importance of a maize-based diet is that it is associated with the period of greatest expansion of the widespread distribution of mound building (Smith 1993, 1995; Milner 2004). But as agriculturally beneficial environments shrank in extent and became increasingly unstable around 1400 CE, the distribution of mound use diminished and the frequency of mound renewal declined. The final blow was struck during the seventeenth century by the persistent slave-raiding expeditions that took place from the Atlantic Coast. These raids undermined the sacred authority of chiefs and the priests that were in charge of political activities associated with mounds before European contact. Dislocations of populations that ensued from climate change led to the abandonment of territories in the Ohio Valley and Great Lakes that centuries before European contact had been the home of a long tradition of mound building. Replacement peoples from the north and east knew little of the mound-building practices.

N

Key Issues

Issues of Scale and Organization

Behind every major earthwork lies the question of how self-sufficient collectors or farmers managed to recruit and direct the necessary labor force behind monument building. It is commonly thought that the more the effort toward constructing a monument, the more the enterprise is likely to be embedded in a complex political organization. However intuitively satisfying this relationship might be, it is reliable only in very broad terms. It cannot be measured off on an interval scale. The social processes inherent in increasing social complexity create structural discontinuities in the capacity to amass labor and other resources. For instance, if large monument construction were calculated by its labor value, then logically these constructions would appear to

be out of range for small-scale economies. Concluding from labor value alone, one might rate the society in question much more complex than other more reliable material indicators would indicate (e.g., subsistence organization, local population sizes). In the case of monuments constructed by mound builders, earthwork mass, to take one term of an equation, has to be scaled in terms of overall labor input and duration of the enterprise. When the three measures are balanced in particular cases, then the short time that field investigation shows it took to erect exceptionally massive mounds, such as Mound A at Poverty Point and Monks Mound at Cahokia, reveals the capacity in those cases to marshal extraordinarily large labor pools (Kidder 2012). However these pools of labor might have been marshaled, the aggregate size is the critical factor. Bear in mind that any enterprise of the magnitude we are speaking of simply cannot afford to interrupt the processes of acquisition and preparation of food. This realization is all the more stark when due consideration is taken of the food resource base of Poverty Point, which is fishing and plant collecting albeit in a highly productive base of aquatic and wetland resources (Gibson 2000). In the case of Cahokia, maize and other cultivated plants yielded comparable productivity to the same kind of wetland/aquatic resource base many miles to the north (Milner 2006).

Centralization of Authority

The matter of adequate-sized labor pool connects with another debate. We have already shown that in two large construction projects, the size of the labor pool available for short periods had to have been drawn from a much wider catchment than usually projected from local support alone. In the case of the large geometric Hopewell earthworks the labor pool likewise does not appear to match the population size that can be mustered from the scattered settlements of rather small size. The ensuing debate revolves around the distribution of population that supported the monumental earthworks of Ohio Hopewell. Since substantial villages have not been found, was the dispersal of population sufficient to provide the construction and support for these mound centers (Byers and Wymer 2010)? The answer has an impact on whether or not pilgrims are dependent upon for labor or whether the local population was sufficient. The relationship between the major multi-mound geometric earthworks and the support population also raises the issue of settlement permanence during the Middle Woodland Period.

This issue touches on the kind of leadership required since planning of the enterprise and coordinating the execution entails uncommon experience and or knowledge (Gibson and Carr 2004). These considerations play heavily into the debate over the matter of social complexity throughout mound builder history (Byers and Wymer 2010). Whereas some scholars have made Poverty Point out to be an expression of chiefly power (Gibson 2000), others have preferred an egalitarian organization because of the fisher-collector economy. Cahokia (IL) has even been placed in its own social category of civilization by calling into question the entire evolutionary scale (Pauketat 2007). One conclusion that can be drawn from these debates is that social evolutionary schemes abstracted from sources outside the subcontinent poorly fit its observed social history. Some have called into question those scales.

Sacred Authority

Other issues come into play. If specialized expertise for mound building is involved how are leaders to acquire it? Does this expertise enter in a significant way into the attainment of political leadership? If they go to far distant places to gain this expertise, do those trips leave traces with hard evidence?

Archaeological investigations have shown that mound building on a small scale can be traced to back to 4000 BCE when more plentifully available food resources made frequent movement of settlements less attractive (Smith 1993). These life-sustaining resources then led, where it was possible, to the entrenchment of claims of ownership and to the planting of burials nearby as a form of certification. These early expressions were usually small and basically made up of mounded cemeteries. Mounds in many cases thereby

became the by-product of the continuity of cemetery usage of particularly important place on the landscape, defined either economically or spiritually. Although the cemetery function of mounds was probably the most widespread usage in time and place, the most conspicuous uses have other functions as well. These are the geometric earthworks of the Hopewell period and the platform mounds of the Mississippian period. From such usages an association of mound burial with spiritual connections developed.

Two of these connections stand out for comment. The first and probably the earliest of these are constructions guided by, if not dedicated to, the observance of celestial risings and settings. The sun is particularly important after 1200 CE, whereas the moon is previously important (Byers and Wymer 2010). The second spiritual connection is as a repository for the remains of the celebrated ancestors (Smith and Miller 2009). The remains of members of the founding lineage were housed in shrines or temples dedicated to their veneration and from whom sacred powers flow to the chief, his living relatives, and his priesthood. The two functions were often combined.

Shrine-based authority for central leadership is largely guided by our text-based understanding of Natchez cultural practices, which have a strong connection with Natchez hierarchical social and political organization. The Natchez case has provided the principle model for chiefdom level of organization in the East. They were organized around matrilineal groups that traced their descent from a tribal semi-deified culture hero. Genealogical seniority was translated into rank with rich clans composing a social tier of nobles. The chief, called the Sun, controlled the tribal ancestor shrine that housed the stone image of that hero as well as the remains of the chief's immediate family and ancestors.

Exotic Material Objects

The subject of spiritual authority leads to a question about it social impact, particularly when such authority derives from features of a sacred place on the landscape. One model is to have people flock in pilgrimages to spiritual places on a regular basis in Hopewell and early Mississippian times (Beck 2003; Byers and Wymer 2010). The attractiveness of this model puts the hosts at spiritual places in the advantageous position of directing visitors in making large monumental projects. The sacred contexts of these projects would be one that would appeal to the circumstances of attraction in the first place. One advantage of this pilgrimage model is that it explains the appearance of large numbers of people that appear to have been enlisted in the colossal mound-building projects. Only the large quantity of food remains need to be documented for brief periods during warm weather.

During the Hopewell Period, quantities of objects and raw materials moved over long distances, coming from peninsular Florida, Ontario, and Yellowstone Park. Some of the largest aggregations of obsidian bifaces and marine shell containers and ornaments ended up in south-central Ohio during the Hopewell Period. A parallel situation at Cahokia exists before 1200 CE in the quantity of marine shell from Florida waters that ended up there (Milner 2006). The question remains was this due to traders departing from the northern centers to acquire valuable raw materials or were visitors from the south journeying north with goods. What part did either of these economic movements take and with regard to the potential role that down-the-line trade played? A finding in favor of journeys to the spiritual places supplies a much needed explanation for the strong presence of exotic goods and the intense periods of mound building that created some of the more spectacular examples of monumental construction in the past.

Impact of Warfare

The impact of deadly conflict until relatively recently was measured by the presence and frequency of fortified settlements. Only with detailed examination of human remains did the record of pervasive violence begin to emerge. That record reveals that the kinds and intensity of violence through time and place were indicative of patterned responses to social, political, and

environmental stresses (Chacon and Mendoza 2007). While episodic flare-ups of deadly violence were present from at least 4000 BCE, continent-wide patterns appeared in the centuries during which local population crowding can be documented. Preceding and during the adoption of maize agriculture is one such period and another is during periods when well-organized polities of aggregated settlers fueled by maize agriculture expand at the expense of less organized groups.

Examples

Relatively early in this history, a large set of earthworks was constructed near the confluence of the Red River with the Mississippi. The Poverty Point is a complex of earthworks spread over 900 acres that was established around 1650 BCE. The central mound of Poverty Point, Mound A, faced a fanlike configuration of six concentric ridges that resembled half of an octagon. Five paths ran through the juncture of the sides from a point radiating from the riverbank. Mound A is aligned with the centerline of this fan. The complicated geometry that underlies this configuration demonstrates the presence of a command of large-scale planning and constructional execution associated with some kind of leadership. Mound A is the second largest mound in the United States by bulk. Archaeological investigation revealed that construction took only 3 months starting between 1450 and 1250 BCE. The planning and execution that went into this monumental achievement is all the more remarkable considering that the supporting economy was based on fish and other wetland resources.

The Hopewell period is the next notable time of extensive mound construction. At this time, mound building was accompanied by an exuberant art style that endured from about 100 to 400 CE with distinct phases therein. The cultural markers of this period are discontinuously present from Florida to the Great Lakes and from the Appalachian mountains to the area of Kansas City. They testify to a new cultural unity among local self-sufficient small-scale gardeners. Major mound groups not attached to local communities were situated in two kinds of locations, either on boundaries between major watersheds or at places uniquely positioned to observe celestial events, in other words places that accessed major sources of spiritual power located in the heavens. Largely small-scale self-sufficient settlements distributed over much of the Midwest and Mid-south were tied by the movement of finished goods and selected raw materials.

The third Mississippian period saw the creation of major earthworks from roughly 1050–1200 CE that appeared to continue the well-established attraction of spiritual centers. The difference was in the population sustaining power of maize agriculture that led to much larger and more permanent settlements. Cahokia was one of the largest such aggregation consisting of 150 ha of occupation and at least 102 mounds of which the central monument, Monks Mound, stands 30 m high with a footprint of 7 ha. This nascent city was in the neighborhood of other large settlements on the floodplain of the Mississippi River, altogether making a large population presence along the Mississippi River. Monks Mound stood in the center of a cruciform of four monumental plazas. Around 1200 CE, social changes took place that greatly increased the number and distribution of townsites through the Midwest and Southeast where maize cultivation was possible in the vicinity of wetland environments. By this time the relationship of population and these resources created the notable distribution of earthworks that provided an identifier for the period. But those earthworks became less important as warfare intensified and Europeans embarked on projects of large-scale trade and colonization.

State of Knowledge and Current Debates

Introduction

This entry spans the entire North American Great Plains and more than 12,000 years. The goal is to present important issues, debates, and data organized in a chronological, geographical, and topical format. Citations were limited as to number, and so review essays are emphasized, especially those covering the broadest range of topics. Sometimes more recent citations were eliminated in favor of earlier, broader ones. Readers wanting details can check references in these essays and do electronic keyword searches. All radiocarbon dates are uncalibrated.

Initial Occupation of the Americas

It is possible North America was occupied as early as 130,000 years ago (Holen et al. 2017). That idea is subject to much disagreement. Until about 20 years ago, America's earliest occupants were thought to arrive through a corridor between the Laurentide and Cordilleran glaciers (Fig. 1). The corridor is available around 13,000 years ago (BP, or before present). Clovis complex represented those peoples. With general acceptance of the 15,000 BP Monte Verde, Chile site, pre-Clovis occupations became more likely.

A Pacific coast route into the Americas is favored now because the ice-free corridor did not exist. The interglacier route becomes a later, secondary path (Meltzer 2009: 5). A third route across northern Alaska and Canada and down the Atlantic coast is also possible (O'Rourke and Raff 2010: Fig. 1). The lack of ancient DNA (aDNA) analyses prevents assessment of whether a particular Plains cultural complex descends from people who followed any of these routes. A proposal that Solutreans from southern France first colonize the Americas receives no support from DNA studies (Skoglund and Reich 2016: 28). DNA research indicates an Asian origin, of some complexity itself, for Native Americans (Skoglund and Reich 2016).

Pre-Clovis

For the Plains, two sites possibly represent occupations earlier than 15,000 years ago, La Sena in Nebraska and Kanorado in Kansas. There are other sites proposed as well going back to 40,000 BP (Holen and Holen 2014: 435). These sites are controversial because stone tools are not present (Kornfeld et al. 2010: 71–73). The Buttermilk Creek complex in central Texas dates between 13,000 and 15,500 BP. This complex includes lithic

North American Plains: Geography and Culture, Fig. 1 North American glaciers and possible routes for occupying the Americas

technology attributes that could be precursors to Clovis (Jennings and Waters 2014). We know little of Pre-Clovis lifestyles. The Plains were potentially settled late, possibly following the Colorado and/or Columbia river valleys (Anderson et al. 2014: 189, 196–199; Erlandson 2014).

Clovis Complex

Clovis represents the earliest Plains occupation about which there is no disagreement. The hallmark is a large, basally fluted projectile point. The flute generally covers only a small part of the point's surface. These points were part of a

spear, lance, and/or atlatl (spear thrower) system. There are a variety of other tools as well (Meltzer 2009: 242–246). Clovis likely develops from people already resident in North America, quite possibly in the Great Plains (Holliday and Miller 2014: 222).

Clovis dates from 11,500 or perhaps even 11,000, to 10,800 BP. This short amount of time implies rapid radiation of either the point style or people across the landscape. Nonetheless, regional variations develop. The complex overlaps the early part of the Younger Dryas climatic event and a change to a colder, wetter climate (Meltzer 2009: 50–60, 254–255).

Lifestyles of Clovis people remain little known. People are often portrayed as moving over great distances. Widespread distribution of high-quality stone tool material types supposedly reflects this mobility. However, other factors, such as trade, could be responsible (Amick 2017). Now-extinct mammoths are seemingly common game. Nonetheless, other large animals plus a wide range of smaller animals are clearly used (Meltzer 2009: 273–279). We know essentially nothing about plant use (Adair 2003: 277).

It is possible, but unclear, that people with other projectile point styles are present contemporaneously with Clovis. Associating dates with these complexes is difficult.

Pleistocene Extinctions/Overkill

Toward the end of the Pleistocene epoch and continuing into the early Holocene, many animal species become extinct or change morphologies, especially size. The question is whether climate change (Younger Dryas) or human hunting pressure is responsible (Meltzer 2009: 255–268). The debate remains unresolved, with new culprits occasionally introduced. Likely both climate change and humans are involved, along with other factors, but to different degrees for each species (Meltzer 2009: 267).

Post-Clovis to 8,000 BP

The largest and most numerous game after 10,000 BP is the bison. Although different bison species are recognized based on morphology, ancient and modern mtDNA studies indicate only one species (O'Shea 2012).

Folsom Complex

Folsom follows Clovis. The hallmark is a projectile point with basal fluting that covers most of both faces. Reason(s) for fluting is unclear. Another important diagnostic tool is ultrathin bifaces used for skinning bison (Meltzer 2009: 295–297, 303). Folsom complex dates between 10,900 and 10,200 years ago. The Younger Dryas (11,000–10,000 BP) is contemporary with Folsom (Meltzer 2009: 284–285).

Folsom potentially derives from Clovis. Earliest dates suggest a northwestern Plains origin (Fig. 2). Folsom replaces Clovis there either through cultural diffusion or actual population movement. On the southern Plains, population replacement is more likely (Collard et al. 2010). Folsom is basically a Plains complex with different complexes appearing elsewhere in North America coming from Clovis and/or Pre-Clovis.

Primary game is bison. Nonetheless, smaller game is more important than traditionally recognized (Hill 2008; Meltzer 2009: 301–302). Although Folsom no doubt exploits wild plant resources, there is almost no evidence (Adair 2003: 277–278).

Folsom points are often of high-quality lithic material moved over long distances. Consequently, Folsom is portrayed as moving significant distances in pursuit of bison (Meltzer 2009: 286). However, exotic materials are restricted principally to projectile points, and these could just as easily be moved through social interaction with other groups.

Folsom people build a variety of structures, especially in the Rocky Mountains region. Some are mud-walled, while others are temporary, more akin to tipis. None are year-round permanent residences but are used seasonally, perhaps repeatedly (Meltzer 2009: 299, 301). If occupations are repeated, then Folsom movement is scheduled and not a free-ranging following of bison.

Late Paleo-Indian

Many different cultural complexes follow Folsom indicating significant cultural diversification and

North American Plains: Geography and Culture, Fig. 2 Plains subareas

likely a reduction in mobility. Most are not well dated. They are considered together here. Climatically a trend begins to a warmer and dryer climate. Most complexes hunt bison, but smaller fauna is far more important than previously thought (Hill 2008).

Lanceolate-shaped projectile point types lacking fluting are diagnostic (Hofman and Graham 1998: 109–113). Late Paleo-Indian complexes generally date between 10,200 and 8,000 years ago (Hofman and Graham 1998: 103). Beginning around 8,000 BP, climatic drying and

warming intensifies, bison begin to undergo a decrease in body size and an increase in herd size, and projectile point styles change to stemmed and notched forms. Late Paleo-Indian origins are unclear and subject to debate but to some degree likely lie in Folsom. Continuities are seen among earlier and later complexes within Late Paleo-Indian as well (Kornfeld et al. 2010: 85–86, 89).

Use of exotic lithics continues, but locally available stone materials increase. Diversification in projectile point styles and increasing use of local lithics suggest an increasing population and movement over smaller areas. Evidence for structures includes temporary shelters such as tipis, whose presence is marked by stone rings, to more permanent constructions having stone-lined walls (Hofman and Graham 1998: 112, 121–122; Kornfeld et al. 2010: 401). The latter may indicate repeatedly utilized base camps. Bison-kill rituals have resemblances to those of historic tribes (Kornfeld et al. 2010: 232–233).

Bison remain the primary game, but the importance of small animals is likely underestimated. Reliance on quick reproducing but harder to catch small prey potentially reflects resource depression in some locations by latest Paleo-Indian times (Hill 2008: 46–47). Little is known about Late Paleo-Indian plant use (Adair 2003: Table 7.2).

There are no aDNA analyses for human skeletal remains from the Great Plains for the period 15,500–8,000 BP. Human skeletal remains are rare. Paleo-Indian and later Archaic populations are relatively homogeneous craniometrically. Homogeneity potentially results from widespread mating networks associated with low population densities (Key 1983: 66).

Plains Archaic Period

Holocene Climatic Optimum (HCO)

Plains climate between roughly 9,000 and 4,500 BP is marked by episodes of pronounced aridity and high temperatures (Grimm et al. 2011). Bison size declines rapidly between 8,000 and 6,500 BP and continues to around 2,000 BP when bison become smaller than modern individuals, especially on the southern Plains (Hill et al. 2008: 1759–1760; Martin et al. 2018). Bison possibly shift their ranges east, west, and perhaps north. Herds are potentially more localized (Widga et al. 2010).

Early Plains Archaic Period

The Early Plains Archaic coincides with HCO. The hallmark is large, stemmed, and notched projectile points of various styles used as part of an atlatl complex. Ground stone implements, such as manos and metates, used primarily to process plant materials increase. A variety of cultural complexes are recognized (Kay 1998: 174–193, Fig. 6.1). Subsequent discussion generalizes across these.

The Early Plains Archaic generally runs from around 8,000 BP to around 6,000 BP. However, there is much variation in dates depending on whether changing projectile point styles or changing subsistence strategies are considered important.

Origins are in earlier Paleo-Indian populations as Late Paleo-Indian projectile point styles and characteristics, along with other artifact types, continue into the Early Archaic, overlapping with new styles and objects (Dyck and Morlan 2001: 115; Vehik 2001: 148; Collins 2004: 118; Jennings et al. 2015: 257). What little human skeletal material there is supports continuity as well (Key 1983: 66; Gill 2010: 533–534).

Because of HCO, it was once thought humans left the Plains, either moving west into the Rockies or east into better-watered locations. However, we now know wholesale abandonment does not occur. Nonetheless, some Plains peoples may move away, but others living outside the Plains may expand into the region (Kay 1998: 173, 185, 188–189; Vehik 2001: 148–149; Jennings et al. 2015: 258). Human population possibly declines.

People live in the best-watered places. Diversification in projectile point and other artifact types along with increased use of local stone suggests people move over smaller areas. Structures likely to be houses are more frequent. These represent repeatedly used base camps. Temporary structures, such as tipis, continue in use (Vehik 2001: 148; Kornfeld et al. 2010: 392, 395–398, 401).

Bison are uncommon and herds possibly are localized. Resource use expands to include not

only medium-size animals such as deer, small animals such as rabbit, mussels, and fish but also baking of bulbs in earth ovens and burned rock features and seed processing with ground stone implements such as manos and metates (Adair 2003: Table 7.3; Collins 2004: 119–120; Johnson and Holliday 2004: 290; Kornfeld et al. 2010: 249–254, 395–398; Widga et al. 2010).

We know little about social and political organization. Small family units and networks of such units (bands) are probably characteristic. Where gathering contributes substantially to food supplies, the role of women in society may be more important (Vehik 2001: 149). The presence of nonlocal materials likely reflects trade rather than the size of space over which people move (Vehik and Baugh 1994: 251).

More speculatively, late in this period movement of people from the intermountain northwest onto the northwestern Plains may reflect an expansion of proto-Algonquian speakers. Mitochondrial DNA analyses indicate Algonquian speakers spread from west to east over the last 3,000–4,000 years (Malhi et al. 2001: 38–41). Historical linguistics analyses produce similar results (Campbell 1997: 152–154). Glottochronology suggests a date of about 5,000 years ago for the origin of Plains Algonquian with eastern Algonquian languages developing later (Holman et al. 2011: Table 6). An east–west trade across the northern Plains at this time is supportive (Vehik and Baugh 1994: 251).

Perhaps proto-Algonquian expansion across the northern Plains is why northwestern Plains craniometrics indicate similarity through time to a sample of modern Algonquians (Gill 2010: 543).

Middle Plains Archaic Period

Large projectile points are the primary diagnostic artifact. Most have a large, broad blade, but there is a diversity of hafting styles. Some use corner, basal, or side notches, while others are simply stemmed. There are many other regionally diagnostic artifacts. Ground stone, primarily used to process wild plants, increases. Burned rock features are common over much of the Plains.

The period begins around 6,000 BP and ends around 4,000 BP. Where beginnings and end dates are set depends upon what individual researchers consider important for defining the period. Increasingly, the end is set at a change to a wetter and cooler climate around 4,400 BP.

Similarities between Plains Middle Archaic projectile point styles and styles outside the Plains are sometimes taken to reflect movements of people. Diffusion of point styles rather than movement of people is seldom considered. It is likely most Plains peoples stay in place adjusting to changing climate and resource conditions, albeit continued population decline is quite possible (Vehik 2001: 149–150; Gill 2010: 534).

People remain hunters and gatherers. Although small herds of bison are present, dental abnormalities among southern high Plains samples suggest bison are under stress, probably from poor range conditions (Johnson and Holliday 2004: 290). Bison size decreases. Most sites with bison are on the high Plains, but bison are occasionally found eastward. Large-scale bison hunting is rarely indicated. Most faunal inventories contain deer and small animals.

Plant resources are primarily wild, although some late sites in the high Plains and Rocky Mountain foothills have maize. Perhaps more important is widespread use of a variety of wild oily and starchy seeds, such as goosefoot, knotweed, smartweed, marsh elder, and sunflower. Some of these will ultimately be domesticated albeit not necessarily on the Plains. *Prunus* begins to appear quite often in botanical assemblages (Adair 2003: 279–286). This genus is consistently used through time and, along with grape, other berries, fruits, and nuts, may be an "encouraged" or "managed" wild plant.

Burned rock middens and earth ovens are used to bake bulbs, roots, shellfish, insects, and meat. Surface water is limited to the point that wells are excavated in several locations on the southern high Plains. Favorable settings with strong springs, streams, or lakes are repeatedly occupied. Houses are uncommon, but pit houses, house basins, and tipi rings are present on both the western and eastern Plains. Mobility is likely high and population densities low. However, both reuse of sites and the occasional construction of burial mounds and cemeteries may mark use

rights to resources. Defined burial locations may also tie dispersed peoples together through ceremonies and feasting. There is not a lot of information on health status, but high dental wear likely reflects use of stone grinding to process food. There are also examples of frequent disruption in bone growth, possibly from food stress. There is little to suggest much difference in sociopolitical organization compared to the Early Archaic (Myster and O'Connell 1997: 151; Kay 1998: 179; Collins 2004: 120–121; Johnson and Holliday 2004: 290–291; Perttula 2004: 375; Kornfeld et al. 2010: 254–255, 392, 401; Whittaker 2016).

In southeast Oklahoma, a series of sites show continuity in artifact styles from the Middle Archaic through later periods when people speaking Caddoan languages occupy the area. People speaking Northern Caddoan languages ultimately come to occupy the Plains from Oklahoma to North Dakota. It may be from southeast Oklahoma that ancestral Northern Caddoans begin their movement out on to the Plains.

Late Plains Archaic Period

Broad-bladed, corner-, or side-notched dart points are the principal diagnostic items. Contracting stem points that may also be knives are present as well. Later, the bow and arrow, marked by much smaller projectile points, may start to appear, especially on the northern Plains. Occasionally pottery occurs late in the period.

The beginning date is increasingly set at around 4,000 BP or to the end of HCO. The ending date is extremely variable. For some parts of the Plains ceramics, smaller projectile points and/or domesticated plants may mark the end date. These appear around 2,000 BP. In other locations, they appear later or not at all, especially domesticated plants. In those cases, the Archaic can extend until after European contact. The terminal date is here set at 2,000 BP.

Changes in projectile point styles often are used to suggest population movements. Mogollon people from the Southwest and Numic peoples (ancestral Shoshone) from the northern Great Basin may expand onto the southwestern and northwestern Plains, respectively. Movements of peoples already on the Plains are also possible. That these new point styles may simply diffuse across the Plains is seldom addressed. Most origins are seen in earlier Plains complexes (Kay 1998: 189; Dyck and Morlan 2001: 123; Vehik 2001: 150). Craniometrics suggest both population continuity and an influx of genes not only from the Great Basin but also from areas east of the Plains (Key 1983: 63–66; Myster and O'Connell 1997: 214–215; Gill 2010: 543, 552).

A marked increase in the number of sites is taken to reflect a population increase. However, decreased erosion and deposition also may increase site visibility compared to earlier (Perttula 2004: 375–376; Kornfeld et al. 2010: 122).

In response to increasing population, mobility declines requiring more use of local resources and a greater variety of food sources, perhaps especially seeds. An emphasis on use of local lithic resources reflects the decline in mobility. A diversity of animal resources is utilized. Bison are important game in most areas (Dyck and Morlan 2001: 121–125; Vehik 2001: 150–151; Johnson and Holliday 2004: 292; Kornfeld et al. 2010: 124–125, 255–260).

Wild plant inventories emphasize nuts and the seeds of goosefoot, pigweed, knotweed, marsh elder, and sunflower. *Prunus* and grape are also present. Cultivated or domesticated plants include squash on the eastern edge of the Plains and maize on the western edge. Most ethnobotanical samples yield wild plants exclusively (Adair 2003: Table 7.3).

Use of burned rock facilities and earth ovens continues (Vehik 2001: 150; Collins 2004: 121; Perttula 2004: 376). Houses include brush structures as well as more substantial constructions such as pit houses. However, tipi rings are frequent, especially on the northern Plains (Kornfeld et al. 2010: 392, 401).

Ossuary and mound burial are documented on the northeast Plains' margin but organized burial programs are uncommon. Health quality varies. In some locations, diet quality may be problematic. Infections and other health-related problems represented by bone growth arrest lines appear occasionally. More common is severe

tooth wear. Cavity rates are highly variable but generally are low with some exceptions. The low caries rate may reflect higher meat intake. Conversely, a higher plant, especially seed, intake may be responsible for the few instances of high cavity rates. It seems health status is mostly good. Evidence for conflict is rare (Myster and O'Connell 1997: 152–153; Vehik 2001: 150; Owsley and Bruwelheide 1996: 190; Gill 2010: 539).

Sociopolitical organization likely remains based on families and networks among families (bands). Where bison are a significant resource, the basic residence group may be larger than elsewhere, at least seasonally, as bison are a clumped rather than dispersed resource. Increasing population and residence group size are associated with increasing political complexity, perhaps involving something similar to tribal systems of political organization. Where gathering provides most food, the status of women is likely higher than where animal hunting is most important.

Trade increases (Vehik and Baugh 1994: 253). With increasing population and smaller resource areas, interaction networks potentially intensify if not expand in size. However, trade also is a mechanism for status enhancement within the context of increasing political complexity.

With a change to a more mesic climate, people bearing an adaptive strategy focused on forested environments and speaking Caddoan languages may expand westward following stream valleys out onto the southern Plains. Glottochronology indicates ancestral Northern or Plains Caddoan diverged from ancestral Caddoan languages during this period (Holman et al. 2011: Table 6). Speakers of proto-Kiowa and/or Tanoan languages are possibly represented in southwestern Plains Jornado Mogollon assemblages and/or in assemblages from southeast Colorado with Basketmaker affiliations. Craniometric studies indicate continuity with Paleo-Indians – at least on the central and northern Plains (Key 1983: 63–66). On the extreme speculative end, perhaps the latter are associated with ancestral Missouri River and/or Mandan Siouan languages and cultures.

Plains Woodland Period

At the beginning of the period (2,000 BP), the climate is relatively cool and moist. Episodes of drought increase toward the end of the period at around 1,000 BP (Schmeider et al. 2011: 1808). Sedentism, ritual architecture, ceramics, arrow points, and domesticated plants increase in importance. The number of archaeological complexes increases. However, ceramic rather than lithic remains define these. Because pottery is a plastic medium, it conveys more cultural information than do reductive mediums like stone.

Early Plains Woodland Period

If not for ceramics, there is little to differentiate this period from the Late Archaic. On the eastern edge of the Plains, earliest ceramics date to a little before 2,000 BP. Ceramics resemble types in the Illinois area. However, for much of the Plains, the Woodland period is defined by the slightly later appearance of ceramics resembling Illinois Hopewell. In southeast Oklahoma and eastern Texas, ceramic connections are to the lower Mississippi valley, especially Tchefuncte complex. On the southwestern edge of the Plains, ceramics have connections to Jornada Mogollon. Increasing use of ceramics reflects reliance on simmering and boiling to process the small seeds that are becoming important food resources (Johnson 2001: 159; Boyd 2004: 317; Perttula 2004: 376; Kornfeld et al. 2010: 62).

Although large dart points resembling those of the Late Plains Archaic continue, smaller points representing the bow and arrow increase. Not all researchers agree on how to recognize bow and arrow technology when only the stone point remains (Dyck and Morlan 2001: 122–123; Boyd 2004: 314, 328–329; Johnson and Holliday 2004: 292).

Domesticated plants increase. Nowhere on the Plains do domesticates provide a majority of the food supply though.

Few sites on the Plains show connections to Early Woodland period ceramics of the eastern United States. Thus, this study defines the Early Plains Woodland period as dating between 2,000 and 1,500 BP (CE 0–500).

Strong similarity of most Early Plains Woodland material culture to that of the Late Archaic indicates most people remain where their ancestors lived (Johnson and Holliday 2004: 292; Logan 2006: 76–84). There are some exceptions. Most notable is Kansas City Hopewell centered on the juncture of the Kansas and Missouri rivers. It is still unclear whether this complex reflects a movement of people from Illinois or contact with people in Illinois or a complex mix of both (Logan 2006: 76). Craniometric analyses indicate Kansas City Hopewell is quite distinct from other Plains Woodland populations (Key 1983: 69, 71, 93, 105) suggesting an intrusive population.

On the southwestern Plains, Jornada Mogollon affiliated groups are also possibly intrusive (Boyd 2004: 296). Biological and archaeological evidence for population change exists in the northwestern Plains' Besant complex as well. But biological change is not consistently evident in all members of the complex (Key 1983: 71). Appearance of new projectile point styles is often taken to represent new peoples or movement of peoples, but diffusion of point styles across people is seldom considered. Sometime after 1,700 BP, Plains elements appear in northern Fremont complex of the Great Basin, possibly introduced by ancestors of southern Athapaskans (Apache and Navaho) perhaps represented by the Promontory Point complex (Dyck and Morlan 2001: 125–127, for more details on the Athapaskan issue see articles in Seymour 2012). Mitochondrial DNA studies suggest Fremont in the Great Salt Lake area is related to Puebloan (Anasazi) people of the Southwest and not Athapaskans, however (Kaestle and Smith 2001: 4).

Most plant resources are wild. Emphasis is on seed-producing plants, although nuts, bulbs, and roots remain in use. Berries and fruits increase. Maize is in some high Plains and northern Plains sites. Domesticated sunflowers, squash, tobacco, and marsh elder occur occasionally (Adair 2003: Tables 7.5–7.10). Chipped stone double-bitted axes increase (Perttula 2004: 376). Possibly these reflect clearance for crop planting. However, more consideration needs to be given to woodland thinning for management of wild resources such as nut trees, fruit trees, and berry vines.

Bison kills take place just east of the southern high Plains but are increasingly uncommon farther eastward (Boyd 2004: 318, 328; Johnson and Holliday 2004: 292–293). Bison are more frequent northward (Dyck and Morlan 2001: 124–125; Johnson 2001: 162–165).

Based on increased site numbers, population continues to grow. Population on the northwestern Plains reaches its height by 1,500 BP (Kornfeld et al. 2010: 130).

Burial mounds exist the length of the Plains, especially in eastern areas. Their inspiration is traced to the Mississippi River Valley, especially Illinois Hopewell and Marksville complexes (Johnson 2001: 161–162; Perttula 2004: 377, 388; Gill 2010: 534–535). These mounds involve obvious alterations of the landscape and likely mark use rights to certain areas. That a group's ancestors are buried there reinforces those rights.

Structures considered to be houses increase. These are circular to oval in outline. Stone foundations mark some central high Plains houses. Increased house construction suggests declining mobility or repeated returns to certain locations. Stone tipi rings are common on the northern Plains (Boyd 2004: 328; Perttula 2004: 377; Kornfeld et al. 2010: 392, 398, 401). Tipis may be present elsewhere but possibly held down by more perishable materials such as wood or bone.

Bison pound or corral construction increases on the northwestern Plains. Some are used and repaired repeatedly. Shaman huts are nearby (Kornfeld et al. 2010: 260–268). Again, this suggests smaller exploitation areas.

Cooking by roasting pit and hot rocks declines. Wylie pits in North Central Texas are roasting ovens for processing abundant, but seasonally limited, root and nut resources. Feasting and mortuary events also take place here (Vehik 2001: 153). Feasting is a potential response to declining mobility as it facilitates interaction with others. Feasting is also a mechanism by which political leaders increase power. Ceramic vessels used to boil and simmer increasingly replace hot rock cooking.

Information on health and diet is not available specifically for the Early Plains Woodland period. Tooth wear rates tend to be high and caries rates

low. High wear reflects use of resources, probably seeds, processed through stone grinding. Caries rates suggest higher meat consumption. Episodic stress rates can be comparatively high. Malnourishment is occasionally indicated. Decline in life expectancy starts to take place on the northwestern Plains. On the southern Plains, however, health appears good (Owsley and Bruwelheide 1996: 190, 193, 196–197; Myster and O'Connell 1997: 159–160, 222; Perttula 2004: 377). Conflict seems to increase across the Plains (Myster and O'Connell 1997: 159, 222; Boyd 2004: 309–311, 330). Potentially an increasing population is responsible for at least some of these trends.

Trade increases and can serve to tie less mobile populations together, thereby reducing risk from famine and conflict. Trade also provides a mechanism by which political leaders can increase power. Interaction of some Plains groups with Hopewell and Marksville is indicated, but nothing suggests Plains groups consistently provide commodities to the Hopewell trade network (Vehik and Baugh 1994: 254–255).

People depending on bison hunting likely have larger social groups at least seasonally. Males have greater status and authority in such societies. Increasing population size and dependence on smaller areas for resources can facilitate increasing political complexity. Nonetheless, most political systems were probably similar to band and tribal organizations.

More speculatively, Northern Caddoan languages must be expanding their distribution northward. Although this expansion is assumed to involve population replacement, craniometric analyses place Keith variant of the central Plains (an often postulated Northern Caddoan group) closer to northern Plains complexes that are likely ancestral to Missouri Valley or Mandan Siouan people (Key 1983: Figs. 15, 18). Possibly, the expansion of Northern Caddoan languages is accomplished through intermarriage and cultural assimilation as much as by actual population movement.

Algonquian peoples continue to live on the northern Plains. However, there is little agreement on which complexes represent them.

Tanoans, possibly including the Kiowa, may be represented in Jornada Mogollon-related complexes of Southwest and West Texas. There also may be Tanoan speakers in southeast Colorado since some complexes there have Southwest connections. Kiowa origins perhaps are better sought in southeast Colorado among groups with Southwest cultural affiliations and high Plains adaptations.

Late Plains Woodland Period

Small projectile points become common after 1,500 BP, especially corner-notched forms often called Scallorn. Ceramics increase, although some western complexes show little to no use of them (Johnson 2001: 166–171; Vehik 2001: 153–154; Boyd 2004: 314; Collins 2004: 122–123).

The beginning date is commonly set at 1,500 BP (CE 500). This coincides with an episode of drought. The end date is set at 1,100–1,000 BP (900–1,000 CE) when several cultural and climatic changes take place. In the extreme southern and northwestern Plains, 1,500 BP marks the start of the Late Prehistoric period.

Continuity in culture and population is likely. In some cases, Early Plains Woodland complexes continue into this period. There are a few exceptions to continuity nonetheless. The spread of small arrow point styles and ceramic attributes are often taken to indicate actual movements of people. Thus, expansion of Southwest, Athapaskan, Numic, and Algonquian peoples is proposed, even though some may already be resident on the Plains from earlier. Diffusion of point and ceramic styles across populations is only occasionally addressed (Key 1983: Fig. 15; Dyck and Morlan 2001: 125–127; Johnson 2001: 166–170; Boyd 2004: 296–329; Perttula 2004: 376–377; Logan 2006: 84–85; Kornfeld et al. 2010: 131).

Site numbers increase, and more cultural complexes are recognized. Together they suggest an increasing population (Logan 2006: 88).

Bison decline east of the central and southern high Plains. This is possibly in response to drought. The northern Plains seem unaffected. Central and southern Plains peoples rely more on seeds and nuts along with a diversity of smaller game animals. Most plant foods are wild. Bulbs

and roots seem less common except perhaps on the high Plains. Domesticates involve mostly maize, sunflower, squash, and marsh elder (Johnson 2001: 166–170; Vehik 2001: 155; Adair 2003: Tables 7.5–7.9; Boyd 2004: 307, 318–321; Kornfeld et al. 2010: 398).

Greater investment in facilities construction suggests repeated or long-term use of a location. Houses are found in almost all parts of the Plains. Predominant house outline is oval to circular. Framework is lightly built. In the high Plains of Colorado and New Mexico, use of dry laid masonry perhaps reflects some connection with the Southwest. Tipi rings are frequent on the northern and northwestern Plains. Residences generally are loosely distributed across the landscape either singly or in small groups (Johnson 2001: 166–168; Boyd 2004: 304–307, 328; Perttula 2004: 377; Logan 2006: 84–86; Kornfeld et al. 2010: 398).

Storage pits are present in more sedentary settings (Johnson 2001: 165–168; Boyd 2004: 304–307, 317). Most are used to store food. People store food where resource productivity is highly seasonal and/or insufficient to supply people with food year-round. Storage increases as population grows.

Mound, ossuary, and cemetery burial are all practiced (Vehik 2001: 154; Johnson 2001: 166–170; Perttula 2004: 377–378). The use of planned, spatially restricted burial programs marks use-rights to resources and provide opportunities for social interaction.

Burned rock middens and roasting/baking pits still occur. However, ceramics and boiling/simmering of food increase (Boyd 2004: 305–306; Perttula 2004: 377; Kornfeld et al. 2010: 398).

Bison corrals continue on the northwestern Plains. However, bison jumps are increasingly frequent. While corrals permit taking only a few animals and require fewer humans, jumps can kill large numbers of bison but require more humans (Kornfeld et al. 2010: 269, 272–273). Bison jumps are a possible focus of intergroup gatherings.

There are not a lot of data on health. The information noted for Early Plains Woodland likely is relevant to this period as well.

Skeletal evidence suggests conflict is more frequent on the western edges of the Plains (Boyd 2004: 325–327; Collins 2004: 122–123; Gill 2010: 536). But otherwise, conflict seems infrequent.

Trade is less prominent. Perhaps this is because social groups are more localized and independent (Vehik and Baugh 1994: 255–256). Low conflict rates are supportive of that idea. But declining mobility, increasing storage, and spatial concentration of burials suggest external connections should be important. Potentially, short-distance trade used to build risk-minimization networks is more important than long-distance trade to fund status and power acquisition by political leaders. Short-distance trade can be more difficult to recognize archaeologically. Risk-minimization networks and short-distance trade can produce the regionally similar material cultures seen among Late Woodland complexes.

Dispersal of houses and settlements suggests sociopolitical organization emphasizes families and networks among families. Communal burial programs and bison jumps are episodic events networking dispersed families and groups together. Consequently, political power is potentially weak and dispersed during Late Woodland times.

The expansion of Northern or Plains Caddoans northward likely continues. Problems noted for Early Plains Woodland in tracing this movement remain.

Origins of the Middle Missouri tradition, ancestors of the Mandan, Hidatsa, and Crow (Missouri Valley Siouans) are traced to the Late Woodland of Iowa and Minnesota (Wood 2001: 186, 190). Yet, at the same time, many other Late Woodland complexes on the northeastern edge of the Plains share ceramic similarities both with earlier Woodland and later Middle Missouri tradition complexes (Johnson 2001: 166). Craniometrics emphasize these local connections as well (Key 1983: Fig. 15). Although an expansion of Middle Missouri tradition peoples may take place, perhaps local northern Plains people more often adopt the material cultures and languages of Middle Missouri tradition.

Late Prehistoric Period

The end of Late Woodland and the start of the Late Prehistoric period overlap the Medieval Warm Period (MWP) or Medieval Climatic Anomaly (MCA). The MCA is variably dated. Often it begins at 1,150 BP (CE 850) and ends at 750 BP (CE 1,250). The main characteristic is periods of prolonged drought extending for decades with the first major episode appearing around 1,000 BP (Herweijer et al. 2007: 1354–1357).

Projectile points are small triangular forms. These potentially mark use of the compound, reflex bow. Ceramics increase greatly. They are frequently decorated with designs that vary both within and between sites. These designs presumably communicate information about group memberships, associations, and beliefs as well as reflect temporal changes in those behaviors. Signaling group memberships or identity may increase in importance with greater competition for resources within and between social groups.

Domesticated plant use increases significantly and possibly rapidly. Bison increase their numbers and range as well. The strategies used to integrate these resources into human life help define the period.

Several cultural traditions mark the Late Prehistoric (Fig. 3). Traditions consist of many smaller groups or complexes having similar material cultures through time. Plains Village, Middle Missouri, Coalescent, Oneota, and Caddoan traditions are most significant.

In this study, the Late Prehistoric period is divided into three parts, Late Prehistoric I, II, and III. Although this subdivision is not common practice, the divisions reflect substantial changes in lifeways.

Late Prehistoric I

Domesticated crops, especially corn, increase. There is overlap between small corner-notched (Scallorn and other styles) points and small, triangular points with side notches and sometimes a basal notch. Numerous cultural complexes are defined based primarily on differences in ceramic decoration.

Date is 1,000–750 BP (CE 1000–1,250). The period co-occurs with MCA.

Origins of most Late Prehistoric I complexes lie in the preceding local Late Woodland (Drass 1998: 423, 429–430, 440; Gunnerson 2001: 234; Henning 2001: 222, 225; Johnson 2001: 172; Wood 2001: 190). Population movements do occur, however. The Middle Missouri tradition expands westward into the Dakotas following the Missouri River Valley. At the same time, resident populations are incorporated into the tradition as well (Key 1983: Fig. 17; Wood 2001: 190).

Oneota tradition begins westward expansion from Wisconsin. Oneota represents people with Chiwere-Winnebago and Dhegiha Sioux languages, perhaps more the former than the latter. Both population replacement and incorporation of local people occur (Henning 2001: 229–233). An example of Oneota incorporation of locals is western Illinois Oneota where ancient mtDNA haplotype distribution is very similar to that for modern Algonquians instead of Siouans (Eshleman et al. 2003: 10).

People from Cahokia, at the junction of the Missouri and Mississippi rivers, are sometimes proposed to move west to the junction of the Kansas and Missouri rivers where they establish a bison procurement operation. Material culture from the proposed colony, Steed-Kisker complex, is mostly of types common to the Plains Village tradition, however. Steed-Kisker craniometric similarities are strongest with Plains Village tradition as well (Key 1983: 89, Fig. 21; Steinacher and Carlson 1998: 254–255). Steed-Kisker is not a Cahokia colony.

The Plains Village tradition represents people who mostly speak Northern or Plains Caddoan languages. Central Plains Village tradition complexes are ancestral primarily to various groups of Pawnee, while southern Plains Village tradition complexes are principally ancestral to various groups of Wichita. Some members of the Plains Village tradition may expand westward on to the high Plains where they depend more upon hunting than farming. However, other possibilities include seasonal-only (summer/fall) use of the region or local hunter/gatherer adoption of Plains Village material culture (Gunnerson 2001: 234).

North American Plains: Geography and Culture, Fig. 3 Late Prehistoric period cultural traditions

Late in the period, central Plains Village tradition people may move northward abandoning, at least partially, more western locations. Central Plains Village tradition craniometrics indicate people in more northern locations are distinct from those in southern locations, though (Key 1983: 79–83, Fig. 18). Thus, to reiterate, movement of Northern Caddoan languages northward is as much about incorporation of local residents as it is their replacement.

Population increase is often invoked in explanations for the spread of Plains Village, Middle Missouri, and Oneota traditions. The number of sites certainly increases, and so population likely grows. However, on the northwestern Plains, population declines (Drass 1998: 428; Wood 2001: 190; Kornfeld et al. 2010: 130).

Subsistence varies. Wild plants are sometimes still the only resources utilized, especially in western areas. Domesticated plant use increases eastward. Bison increase on the western edge of the Plains. On the northwestern Plains, corrals, jumps, and arroyo traps show repeated use. Eastward deer are more often used (Drass 1998: 424, 429, 433; Steinacher and Carlson 1998: 246, 250, 253–254; Dyck and Morlan 2001:

N

128; Henning 2001: 227; Adair 2003: Tables 7.11, 7.13, 7.16; Kornfeld et al. 2010: 268–276). People use resources that are locally available, supplementing them with farm products.

Houses are more substantially built, especially among farming peoples. Plains Village, Coalescent, and Middle Missouri tradition complexes construct square or rectangular houses. Houses on the southwestern Plains sometimes have stone foundations and can be built contiguously reflecting possible influences from Pueblo architecture. Stone circles reflect use of tipis. In the southern and central Plains, houses tend to be sparsely distributed along drainages, either singly or in small groups. Larger groupings occur in the Caddoan tradition and in the northern and northeastern Plains. Fortified villages occur in Middle Missouri tradition (Drass 1998: 423, 428–429, 432–433, 439; Johnson 1998: 313, Fig. 10.4a, b; Steinacher and Carlson 1998: 241, 245, 248–249, 252–253, 256; Wood 2001: 192; Perttula 2004: 379–385; Kornfeld et al. 2010: 398–399, 401).

Storage pits are important among sedentary farmers but do not occur in large numbers except perhaps on the northern Plains. Predominantly they are either bell-shaped or cylindrical in profile (Drass 1998: 429, 433, 439; Steinacher and Carlson 1998: 241; Henning 2001: 224–226; Wood 2001: 188). Analyses of storage pit size and density could provide information on the extent to which various groups of people rely on stored resources and likely farming.

Mound construction in the Caddoan tradition is used both for elite burial and elevation of elite residences. Mound and ossuary burial continue in some parts of the central and northern Plains. However, in general, mound and ossuary burial seem in decline, except on the northeastern Plains. Cemeteries increase and some may serve multiple villages or hamlets. On the northwestern Plains, burials are placed in crevices or exposed (Steinacher and Carlson 1998: 242, 246, 250, 254, 257; Dyck and Morlan 2001: 128; Henning 2001: 224–226; Perttula 2004: 379–384; Gill 2010: 536, 540).

With increasing use of maize and consumption of carbohydrates, caries increase. Tooth wear declines in a few places suggesting a less abrasive diet and perhaps ways of processing grains other than stone grinding. Incidences of episodic biological stress lessen, possibly because the food supply is more stable and sufficient. Stress does not disappear completely, however. On the northwestern Plains, people are perhaps not doing well since the average age at death declines. Increased competition for food under a high population density may be responsible. The caries rate in this area declines reflecting an increase in the consumption of bison meat compared to high carbohydrate plant foods (Owsley and Bruwelheide 1996: 190, 193–197; Myster and O'Connell 1997: 164–171, 228; Gill 2010: 539, 546). The MCA does not seem to have a strong negative effect on human health.

Conflict increases (see articles in Clark and Bamforth 2018 for detailed explorations of Plains warfare during the Late Prehistoric). Both hunter/gatherers and farmers are involved. The exact cause of conflict is unknown. Athapaskans moving south and east and Puebloan peoples moving east may be responsible on the west-central and southern Plains (Drass 1998: 423; Steinacher and Carlson 1998: 254; Wood 2001: 190–192; Collins 2004: 122–123; Gill 2010: 536, 546–548). Competition over access to bison and farm land may be important as well.

Trade increases both among Plains groups and with people living outside the Plains. Stones and ceramics are most easily identified, but, no doubt, other, more perishable, resources such as bison products are also traded. On the southeastern edge of the Plains, the formation of complex political systems among Caddoan tradition members is associated with acquisition of many Plains resources. Trade increasingly is for political purposes rather than for food or technology resources (Vehik and Baugh 1994: 257–259; Vehik 2002: 44–51).

Given dispersal of houses and settlements, political systems emphasizing networks among families are likely. Many cultural complexes grade into one another rather than having sharp boundaries, which suggests politics involves local, fluid networks of relations, probably much like tribal organizations. Nonetheless, planned, visible, and spatially restricted mortuary practices

indicate rights to resources remain important. In some places, the construction of special ritual structures, concentration of nonlocal materials at one or a few sites, and multicommunity mortuary facilities suggest access to political power and resources has some inequalities within and between communities. This is most pronounced among Caddoan tradition societies.

Expansion of the Plains Village, Middle Missouri, and Oneota traditions possibly is a result of farming with the greater food supply fueling population growth and expansion but also causing land exhaustion. Yet, climate conditions do not seem that favorable to farming, and craniometric data suggest less actual movement than commonly assumed. Instead, perhaps because of long periods of drought, farming (and increased storage) is added to diversify subsistence. Plains Village tradition expansion is possibly most successful precisely because it maintains a more diversified subsistence.

Late Prehistoric Period II

The predominant point style is small, triangular, and side notched. Bison procurement and processing tools are common. Use of ceramics increases. Farming tools such as grinding stones, bison shoulder blade hoes, and bison tibia digging stick tips are frequent.

While some climatic researchers suggest a cooler and wetter climate starting around 800 BP (CE 1,200), others continue MCA through this period. The MCA may end abruptly around 600 BP (CE 1,400) (Herweijer et al. 2007: 1354). Some sites from Late Prehistoric I are covered by wind-blown dust as are some sites from this period (Johnson 1998: 328). Climatic conditions are likely comparatively dry.

This period extends from 750 to 600/550 BP (CE 1,250–1,400/1,450). The end is marked by major environmental and cultural changes.

Many complexes descend from those of Late Prehistoric I or are continuances of those complexes, but there are exceptions (Drass 1998: 421–422, 430, 433, 439; Johnson 1998: 313, 327–328; Steinacher and Carlson 1998: 244, 248, 255–256; Gunnerson 2001: 234; Wood 2001: 192–193). The problem of material culture similarities not agreeing with craniometric analyses continues. Some complexes on the southwestern Plains have a southern Plains Village tradition material culture, but craniometrics indicate a lack of similarity to other Plains Village tradition cultures. Neither do these groups resemble earlier populations (Brooks 2004: 335). Other southern Plains groups adopt a southern Plains Village tradition bison hunting material culture as bison populations increase and expand (Vehik 2001: 155–156; Collins 2004: 122–123, 125).

The Missouri River Valley in the northern Plains is a favorable location for farming. Not only are many members of the Middle Missouri tradition resident along the Missouri River, but other related groups may move into the valley from elsewhere (Wood 2001: 193). Craniometrics supports the idea of diverse origins for people of the Middle Missouri tradition as noted earlier (Key 1983: Figs. 17, 19).

Several complexes in eastern North Dakota, western and northern Minnesota, and southern Manitoba and Saskatchewan potentially represent Siouan and Algonquian peoples. These complexes appear to move northward and westward (Dyck and Morlan 2001: 128–129; Henning 2001: 230). Perhaps they do so in pursuit of bison.

A new tradition, the Coalescent, has origins in central Plains Village tradition (Northern Caddoans) – at least to some extent (Johnson 1998: 327–328). Expansion of Coalescent tradition north along the Missouri River pushes Middle Missouri tradition people northward.

Population may increase, but toward the end of the period, significant rearrangements of people begin. There is population movement and amalgamation, but there also may be population loss (Drass 1998: 422, 431–432).

Many Plains peoples intensify farming, but some remain hunter/gatherers. Bison increase in numbers and distribution. They are the primary game for most Plains peoples (Drass 1998: 421, 431, 433; Steinacher and Carlson 1998: 255; Gunnerson 2001: 235–236; Henning 2001: 229; Vehik 2001: 155–156; Wood 2001: 188; Adair 2003: Tables 7.12, 7.13, 7.14, 7.16; Collins 2004: 122–123; Perttula 2004: 383).

While farmers are associated with relatively permanent houses, some bison hunters have seasonal village residency in similar houses. Houses are mostly square or rectangular. Structures with circular floor plans occur on some Plains Village and Coalescent tradition sites but are most common on Caddoan tradition sites in east Texas. Houses with stone foundations are constructed in the southwestern Plains. Some are built contiguous to one other, like a pueblo. Although some houses continue to occur singly or in small groups scattered along stream drainages, larger clusters exist in almost every complex. It is not clear what prompts formation of larger aggregations. Conflict is likely involved to some degree, as may be social and economic opportunities some communities might offer over others (Drass 1998: 419, 425–426, 430–432, 440; Johnson 1998: 313; Steinacher and Carlson 1998: 255; Wood 2001: 193; Perttula 2004: 379, 382).

Storage pits are extremely common, especially among farmers (Drass 1998: 419, 425, 430, 433, 440; Henning 2001: 229; Wood 2001: 188; Perttula 2004: 379). Along the southeastern edge of the Plains, aboveground storage facilities are also indicated (Perttula 2004: 379, 382–383). They are likely also present elsewhere. With increasing reliance on seasonal food production through farming, along perhaps with periodic drought episodes, the need to store food increases.

Among Caddoan tradition societies on the southeastern edge of the Plains, burials are placed in mounds and cemeteries. These reflect complex sociopolitical systems and differential access to wealth, power, and authority. Mound building and ossuary construction decline elsewhere. Cemetery burial increases. The presence of a few large cemeteries in association with some villages suggests multicommunity mortuary practices. These perhaps maintain the communal aspects of mound and ossuary mortuary rituals while introducing new, more hierarchical features. Some Plains Village tradition complexes may also have charnel or other specialized mortuary houses. In some cases, there is no evidence regarding how deceased society members were treated. Scaffolding or other forms of exposing the dead may be indicated by this lack of mortuary evidence (Drass 1998: 419, 423–426, 430, 439; Johnson 1998: 313–316; Perttula 2004: 379–386). Important shifts in mortuary ideology are suggested, but their nature is unclear.

Residence in villages and reliance on high carbohydrate diets impacts health. Southern Plains Village tradition people have high preadult mortality, but older adults live longer compared to those from farther north and later in time. Caries and alveolar bone pathology rates for the southern Plains are high. This suggests a high carbohydrate intake. Earliest Coalescent tradition skeletal material indicates a rate of episodic biological stress higher than in southern Plains Village tradition groups. The rate is also higher than in later Coalescent groups (Owsley and Bruwelheide 1996: 162–3,190, 193–194, 196, Table 70). Much more research is necessary to substantiate and reconcile these features and define their causes.

Violence is common. Depending on location, settlements emphasize high locations such as mesas, peninsula settings having commanding valley views, large village size, closely spaced settlements, abandonment of areas once occupied, and fortification. Skeletal trauma is widespread. The best testament is the Coalescent tradition Crow Creek village where over 500 people were massacred. Caddoan tradition iconography emphasizes violence, albeit that violence is not very visible in archaeological remains (Drass 1998: 422–423; Johnson 1998: 313, 316; Gunnerson 2001: 236–237). It is not clear who is fighting whom or what the reasons for conflict are. Access to bison, interethnic relations, competition for farmland, status acquisition, and retaliation for grievances may all be involved. Although not recognizable in material culture assemblages, Athapaskan ancestors of the Apache and Navaho must be moving south and east onto the high Plains.

Some earlier trade relations cease, but trade between Plains groups intensifies as does trade with groups in surrounding regions (Vehik and Baugh 1994: 259–261). What is archaeologically visible today are nonlocal shells, stones, and ceramics with some of the latter often being local copies of what must be more prestigious

wares. Trade in bison hides, skulls, meat, and tool bones are of possible equal, if not greater, importance. Explanations for how and why trade intensifies are many. Most emphasize mechanisms for obtaining food. However, political intensification potentially results in greater emphasis on nonlocal materials as markers of inequalities (Vehik 2002).

Sociopolitical organization increases in complexity among many. For Caddoan tradition peoples, this is the time of maximum political complexity similar to chiefdoms. Many Plains Village tradition sites have structures whose large size, form, placement, and/or content indicate specialized ritual or political activities. Some Middle Missouri tradition villages also are organized around central plazas (Brooks 1987: 142, 151; Brown 1996: 183–191; Gunnerson 2001: 236; Wood 2001: 193; Perttula 2004: 380, 382–386). Given specialized ritual and political structures, patterned village layouts, and labor organization necessary to design and construct increasingly sophisticated fortifications, it is likely most Late Prehistoric II societies are more complexly organized than earlier.

Late Prehistoric Period III

Significant cultural changes start taking place with the end of Late Prehistoric II. The changes are poorly understood but involve pronounced social change and population movement.

This period coincides with the Little Ice Age (LIA) climatic episode. When LIA begins and ends is not agreed upon, but usually the starting date is around 600 BP (CE 1,400). The transition is abrupt. For the Plains, temperatures are colder and precipitation increases, albeit moisture remains on the dry side. Changes on the northern Plains may be greatest. Although favorable for farming, studies suggest dry growing seasons – at least in some places. Droughts occur but are not as severe as during MCA. Bison numbers and distribution expand greatly (Herweijer et al. 2007: 1354; Lohse et al. 2014).

The primary projectile point style remains a small triangular form, but most are not notched. Tools associated with bison processing increase. Ceramics increase in frequency, especially among farmers. Among horticulturists, crop production and processing tools are numerous.

Late Prehistoric III starts between 600 and 550 BP (CE 1,400–1,450). Setting a termination date is somewhat arbitrary. Sometimes a terminal date is determined by the appearance of Europeans. That varies, however, as Europeans visit the southern Plains in CE 1,541, while on the northern Plains, it may be more than two centuries later. The termination date is set here at 350 BP (CE 1,650). There is little evidence for Europeans having much influence or presence on the Plains prior to that date.

The Arkansas River Valley member of the Caddoan tradition begins the period with exhumation of the dead and their reinternment in a massive mound construction event. Although perhaps reflecting the maximum political complexity achieved in this area, there is soon a decline. Sometime in the late seventeenth century CE, the Arkansas River Valley Caddo abandon a place lived in for several thousand years, move south, and become the Northern Caddoan-speaking Kichai. Caddoan tradition people living in east Texas and adjacent areas show less abrupt change. They are ancestors of various Caddoan groups such as the Hasinai and Kadohadacho (Brown 1996: 187, 191–200; Perttula 2004: 393–407).

Southern Plains Village tradition people abandon some places lived in for 400+ years. Why is unclear. Climate changes unfavorable to farming are perhaps responsible. However, potentially bison hunting becomes more productive than farming, instigating abandonment of farming. Increasing conflict may encourage people to move. Changes begin early in the fifteenth century CE. Farmers from different southern Plains locations coalesce along the eastern Plains margin, while bison hunters dominate western areas. Coalescing farmers and some of the mobile bison hunters are ancestors of the Northern or Plains Caddoan-speaking Wichita (Drass 1998: 422, 424–425, 431–434, 441–444; Vehik 2001: 156–157; Johnson and Holliday 2004: 293).

Central Plains Village tradition peoples reside in central and northern Nebraska. They farm and

hunt bison. They are ancestors of the Northern Caddoan Pawnee and perhaps of some Arikara. It is difficult to trace precise relationships through material culture or craniometrics (Key 1983: Fig. 21; Steinacher and Carlson 1998: 258–259).

The Coalescent tradition includes ancestors of the Arikara and possibly part of the Pawnee. This issue is complex, both biologically and culturally, and is not well understood. Coalescent tradition expands northward. They farm and hunt bison (Key 1983: Fig. 21; Johnson 1998: 309, 327–331; Steinacher and Carlson 1998: 258–259). They may make greater use of wild resources than does Middle Missouri tradition.

Members of Oneota tradition maintain a strong presence on the eastern edge of the central Plains. They farm and hunt bison farther out onto the Plains as well. Connections with Historic Plains groups are complex and difficult to trace (Key 1983: 86, 96; Henning 2001: 229–230, 232–233).

Middle Missouri tradition people move northward along the Missouri River, pushed by Coalescent tradition. If the Crow do not split from the Hidatsa earlier, they do so now. Middle Missouri tradition farms heavily and hunts bison. Other complexes with strong similarities to Middle Missouri tradition live to the north of the Missouri River, but their relationships are unclear. They farm to varying degrees and hunt bison (Johnson 1998: 329; Dyck and Morlan 2001: 129–130; Wood 2001: 194).

Athapaskan ancestors of the Apache meanwhile are moving on to the western Plains. Two associated complexes are Dismal River in southwest Nebraska and northwest Kansas and Tierra Blanca in the Texas panhandle (Gunnerson 2001: 239; Vehik 2001: 156). They are strongly associated with bison hunting.

Ancestors of several other historically known ethnic groups are likely on the Plains at this time. They include the Kiowa, Arapahoe, Gros Ventre, Dakota, Assiniboine, Blackfoot, Plains Cree, and others. However, making connections to specific archaeological complexes is difficult, and there is much disagreement (Hanson 1998; Dyck and Morlan 2001).

Both population decline and increase are proposed. Impressions of increase may come from coalescence of people in a few locations, while decreases may reflect abandonment of other areas. European epidemic diseases do not seem a problem for the Plains until after 1,650 and so is an unlikely cause of depopulation (Vehik 1994: Table 11.5; Perttula 2004: 398, 403, 406). Warfare is common and a potential source for movements leaving impressions of population increase and decrease (Steinacher and Carlson 1998: 259).

Subsistence is more specialized, emphasizing farming or bison hunting – not to say that doing one precludes the other. Farming tends to be more conspicuous on the eastern Plains and bison hunting on the western Plains. Domesticates are corn, beans, squash, and sunflower. A variety of wild fruits, nuts, and seeds are collected, and their growth likely encouraged. A marked increase in bison jumps after CE 1,500 in the northwestern Plains no doubt reflects larger bison populations (Drass 1998: 443–444; Dyck and Morlan 2001: 129; Gunnerson 2001: 240; Vehik 2001: 156–157; Wood 2001: 188; Adair 2003: Tables 7.12–7.14, 7.16; Perttula 2004: 394, 405; Kornfeld et al. 2010: 131; Lohse et al. 2014).

Sedentary farmers construct substantial houses. Circular floor plans increasingly replace rectangular or square designs. Some full-time bison hunters maintain villages where they are seasonally sedentary. Stone rings mark the use of tipi-like structures. Particularly among farming groups, structures are much less often strung out across the landscape. Not uncommonly villages are quite large (Drass 1998: 440, 443; Johnson 1998: 318; Gunnerson 2001: 240; Vehik 2001: 156–157; Wood 2001: 194; Perttula 2004: 393, 395, 399; Kornfeld et al. 2010: 401).

Farmers have many storage pits. They are larger and more numerous than earlier. This reflects increased dependence on maize farming – both for subsistence and trade. Storage facilities are smaller and fewer among bison hunting and foraging peoples (Drass 1998: 440, 443; Gunnerson 2001: 240; Henning 2001: 229; Vehik 2001: 156; Wood 2001: 188; Perttula 2004: 395, 398).

Mound construction declines in the Caddoan tradition and is rare elsewhere. Interment of the

dead becomes increasingly uncommon among farmers as well as hunters and foragers. The lack of burials suggests the use of exposure (Johnson 1998: 319; Henning 2001: 230; Wood 2001: 188; Perttula 2004: 393–396, 400–404). Changes in Plains mortuary practices from interment in earth to exposure above ground culminate in this period. The causes are unclear but may reflect the idea that burial underground brings the deceased closer to the underworld while scaffolding and exposure brings them closer to the above world.

Absence of burials results in much less information on health. Caddoan tradition health conditions overall are good. The northwestern Plains' caries rate is low probably a result of increased meat eating. Northwestern Plains' skeletal evidence indicates increasing violence against women as bison hunting increases. As hunting is primarily a male activity, the more it contributes to the economy, the less the value of female labor. The less women are valued, the greater the incidence of violence against them (Johnson 1998: 329; Perttula 2004: 393–394, 405; Gill 2010: 546–549).

Conflict is extensive. Fortifications exist on both the southern and northern Plains, but not all sites are fortified. Abandonment of some locations and coalescence in others very likely are defensive measures (Johnson 1998: 318; Vehik 2001: 156–157; Wood 2001: 188). Causes include those mentioned for Late Prehistoric II. Warfare is potentially so intense that people of some cultural complexes may make no genetic contribution to later groups (Steinacher and Carlson 1998: 259).

Trade increases (Vehik and Baugh 1994: 261–264). Possibly this is to temper warfare by establishing intergroup relations facilitated by ceremonies like the Hako/Calumet. Other possibilities include intensifying relationships to mitigate risks of food insufficiency, creating mutualistic partnerships for the exchange of bison and corn, forming a world system centered on the Southwest, and intensifying political complexity (Vehik 2002; Perttula 2004: 406).

Coalescence of once independent social groups, intensifying conflict, and increasing subsistence specialization favor increasing sociopolitical complexity among some, but certainly not all, Plains populations. Some Plains Village tradition settings have specialized structures for ritual and political activities. In other Plains Village, Coalescent, and Middle Missouri tradition complexes, larger lodges in central locations provide similar services. Patterned village layouts and sophisticated fortifications imply some degree of sociopolitical complexity. Among Arkansas River Valley members of the Caddoan tradition, political complexity declines (Johnson 1998: 318; Vehik 2002; Wood 2001: 194; Perttula 2004: 401, 406).

Conclusions

The prehistory of Plains peoples is complex. It involves actual movements of people, but perhaps more important may be culture-switching within the context of a variety of transformative situations. The ethnic groups recognized in the nineteenth century must be understood as a product of long-term development with especially pronounced changes still ongoing at the time of the European intrusion.

North American Rock Art, Fig. 1 Pictographs or rock paintings are common in many regions in North America. Although *red*, made from ocher, is the most common color employed, this is an example of a *black* and *white* bichrome painting from the southern Sierra Nevada, California

North American Rock Art

David S. Whitley
ASM Affiliates, Inc., Tehachapi, CA, USA

Introduction and Definition

Rock art is a landscape art: images created on natural rock surfaces, such as cave walls and ceilings, cliff and boulder faces, and the natural ground surface. North America, especially western North America, has a very rich record of rock art. This includes rock paintings and drawings (pictographs; Fig. 1); peckings, incisings, and scratchings (engravings or petroglyphs; Fig. 2); and intaglios and rock alignments (earth figures or geoglyphs; Fig. 3). Although contemporary and historical Euro-Americans have sometimes created graffiti of various kinds on the landscape, rock art in this discussion is limited to imagery created by Native Americans.

Description

The earliest North America immigrants are assumed to have brought rock art production with them from Siberia. Though the age of this initial colonization is still uncertain, it is thought to have occurred c. 15,000 Years Before Present (YBP) or earlier, with the ultimate antiquity of North American art as yet unknown. Despite this difficulty, growing evidence suggests that rock art was not simply present prior to 10,000 YBP,

North American Rock Art, Fig. 2 Petroglyphs or rock engravings are found throughout North America but are especially common in the desert regions where dark rock varnish coatings provide a distinct contrast with the lighter, underlying heart rock. These examples are from the Coso Range, California

North American Rock Art, Fig. 3 Geoglyphs or earth figures include rock alignments and intaglios (which are scraped into a desert pavement). This example of an alignment is from the Slate Range in eastern California

during the Paleo-Indian period, but that regional traditions had already been established by that time. In the Great Basin and the greater Southwest, a Great Basin Petroglyph Tradition was established by at least 12,000 YBP (Whitley and Dorn 2012; Fig. 4). This is characterized by a wide variety of geometric motifs and figurative images of simple stick-figure humans and bighorn sheep (*Ovis canadensis*). In the northern Plains, Early Hunting Tradition petroglyphs have similar antiquity. They include quadrupeds of various kinds, typically with exaggerated "ball feet," simple humans, nets, and *atlatls* (spear-throwers; Tratebas 2012). On the southern Plains, the Old Incised Tradition consists of fine-lined incised geometric designs (Loendorf 2012). Created as both rock and mobile art, this also may be 12,000 or more years in age. It is likely that

North American Rock Art, Fig. 4 Bighorn sheep petroglyphs from the Coso Range, California, have been chronometrically dated to as early as 11,200 YBP. These early motifs are heavily revarnished, as shown by these examples from an early Coso site

other early regional traditions existed but have not yet been identified, including early painted art (as has been found in South America).

Subsequent rock art illustrates two widespread (but not universal) temporal trends: increasing regionalization and/or greater artistic elaboration and augmentation over time. By roughly 7000 YBP (the Middle Archaic), regional patterns that existed during the historical period began to develop. These approximately follow ethnographic "culture areas" (Fig. 5), as described by anthropologists, signaling the fact that the historical cultural distributions themselves have relatively great time depth.

The Great Basin Petroglyph Tradition, widespread across the west during the early Holocene, retracted over time, ultimately being primarily restricted in a core area consisting of the Great Basin physiographic region. Although the tradition thus has great time depth, change is visible in increasing artistic elaboration (e.g., complex "patterned body" anthropomorphs in addition to stick figures) over time, as well as by the development of localized variants with their own specific stylistic and motif emphases (Whitley et al. 1999). An increase in rock art production also appears to have occurred during the last few thousand years, with the tradition continuing into the historical period.

A distinct California Tradition developed in southwestern California by or shortly after the Middle to Late Archaic (by 3000–4000 YBP) and continued into the historical period (post-230 YBP; Whitley 2000). This primarily consists of pictographs, the majority of which are simple monochrome geometrics and stick-figure humans, lizards, snakes, and other animals. In certain regions, particularly in the Chumash area around Santa Barbara and in the southern Sierra Nevada, bichrome and polychrome paintings were created. Some of this art is quite elaborate if not psychedelic in appearance.

The Northwest Coast Petroglyph Tradition, like the renowned wood carvings and sculptures from this region, is highly conventionalized with a strong iconographic coherence (Keyser and Poetschat 2012). Sites are commonly located on boulders on the coast, at or near the tide line, in

North American Rock Art, Fig. 5 North American rock art is best discussed in terms of nine ethnographic culture areas, as shown here

N

proximity to villages at the mouths of salmon-spawning streams. Motifs emphasize schematized human faces/masks, along with a variety of geometric forms and zoomorphs, such as bears, birds, fish, and sea mammals. The earliest of these sites appear to date to approximately 4000–2000 YBP, with the motifs becoming increasingly conventionalized after that date. The tradition continued into the historical period.

Arctic rock art is rare, consisting of sporadic pictograph and petroglyph sites (Stevens 1974). Motifs are similar to those found in the Northwest Coast Petroglyph Tradition, but lack the conventionalization typical of that adjoining region, and cannot be said to constitute either a recognizable style or tradition. The petroglyphs are believed to date from roughly 1200 YBP but may be earlier.

The Columbia Plateau Tradition includes pictographs and petroglyphs sharing widespread thematic consistency, despite a series of regional stylistic variants (Keyser 1992). The tradition is predominated by simple stick-figure humans, block-bodied animals, rayed arcs, tally marks, "sun" symbols, and other geometric motifs, but the hallmark consists of one or (often) two stick-figure humans standing under rayed arcs. The discovery of both pictograph and petroglyphs panels buried by datable volcanic ash indicates that Plateau rock art began before 7000 YBP, possibly much earlier. More elaborate stylistic variants of the tradition developed regionally after about 1500 YBP, and Plateau rock art continued to be created in contemporary times.

Whereas the rock art traditions described above were created by hunter-gatherers or hunter-gatherer-fishers, the rock art of the Southwest was partly produced by settled farmers, following the development of agriculture approximately 2000 years ago (Schaafsma 1980; Bostwick 2002). One result is a complicated rock art record, reflecting the large series of cultures in this large area. At least five regional styles were present in the Southwest by the Early to Middle Archaic (if not earlier), including a southeastward extension of the Great Basin Tradition, discussed previously. This Archaic/hunter-gatherer substrate includes both pictograph and petroglyphs. Although not universally present, one characteristic of these early traditions is large anthropomorphs (Fig. 6), many of which are elaborately and/or flamboyantly rendered.

North American Rock Art, Fig. 6 The Archaic hunter-gatherer substrate of the American Southwest is notable for large anthropomorphic pictographs found in Utah. This example is from the Head of Sinbad site

A great proliferation of Southwestern styles occurred after about 2000 YBP, during the Puebloan and Hohokam period, with the development of local farming cultures and probably reflecting the appearance of priestly religions and cults (Fig. 7). Pictographs and petroglyphs are again present, with the motifs typically (though not invariably) consisting of relatively simple and regionally conventionalized images. Certain of these styles retracted geographically or disappeared c. 700 YBP, following the Puebloan collapse. The incursion of hunter-gatherers and pastoralists after that event added another layer

North American Rock Art, Fig. 7 The Puebloan farmers of the American Southwest created rock art in a number of contexts, including a ritual salt pilgrimage, where they engraved their clan symbols at the sacred site of Willow Springs. Shown here are bear clan symbols

of complexity to Southwestern rock art, with the appearance of a series of new tribal styles, sometimes with wide geographical extent.

Great Plains rock art, like that of the Southwest, is complex and diverse, again reflecting a changing mix of hunter-gatherers, farmers, and, historically, pastoralists – the famous Plains "horse cultures" that developed following the Spanish reintroduction of the equine into the Americas (Keyser and Klassen 2001; Loendorf 2008). Petroglyphs tend to be most common overall, though pictographs predominate in the northwestern Plains, with designs ranging from simple, crudely pecked geometrics to finely rendered polychrome figurative images. Motifs include geometrics, supernatural beings, war exploits, and a wide range of animals, including especially horse, deer, and elk (wapiti).

The Early Hunting Tradition, on the northern Plains, and Old Incised Tradition, in the south, demonstrate that Great Plains rock art was created as early as 12,000 YBP. The Early Hunting Tradition continued until approximately 2500 YBP, after which a series of more localized styles developed on the northern Plains. The Old Incised Tradition, in contrast, was replaced by the South Plains Archaic Tradition at c. 7000 YBP. The apparently "pan-tribal" Ceremonial Style developed as an overlay across much of the Plains after about 2000 YBP. The Biographic Style appeared c. 400 YBP and continued into the historic period. Like the ceremonial art, it was pan-tribal in distribution and is linked to the historical horse cultures. Much of its art is related to raiding and war (Fig. 8), which were endemic in the region during this period.

Petroglyphs are more common than pictographs in the Eastern Woodlands Tradition which, in addition to these two common kinds of rock art, also includes "mud glyphs" (Diaz-Granados and Duncan 2004). These are images that were scraped into the soft-sided walls of dark-zone caves. Birds are the predominant motifs at Eastern Woodlands sites, with the thunderbird serving as the hallmark of the region. This was a large, supernatural being whose flapping wings caused wind and thunder. Other common motifs include anthropomorphs of various types, including faces, geometrics, animal tracks, various other animals, other supernatural beings, and weaponry. Although some images include significant detail, overall the art is relatively simple and only minimally elaborated. The currently earliest dated Eastern Woodlands art was created about 7000 YBP, but the tradition is likely more ancient in origin. Most of the art appears to date to the last 2000 years however, with much of it reflecting the iconography and beliefs of the widespread

North American Rock Art, Fig. 8 Commemorative rock art, made to memorialize war honors and events, is common in the Great Plains. This example is from La Barge Bluffs, Wyoming

Southeastern Ceremonial Complex associated with the Mississippian culture.

The Northern Woodlands (or Canadian Shield) Tradition primarily consists of monochrome pictographs, though with a concentration of petroglyphs towards its southeastern extreme. Common motifs include a variety of simple humans, often with upraised arms and with variable body shapes; birds; tracks; snakes, lizards, turtles, and various quadrupeds; "mythological beings"; drums and canoes; and geometrics (Rajnovich 1995). The painted sites are commonly located on vertical or near vertical cliff faces that front lakes or rivers, whereas the incised (and occasional pecked) petroglyphs occur on flat horizontal outcrops. The Northern Woodlands Tradition dates as early as 2000 years ago, with the tradition continuing into historical times.

Historical Background

Euro-American intellectual interest in North American rock art began with the writings of the Puritan Cotton Mather, at the beginning of the seventeenth century (Whitley 2001). This sets the tone for the first two-and-a-half centuries of occasional rock art study, which was philologically oriented, emphasizing the putative significance of the art in terms of the origins of writing. An ethnographic approach was introduced in the mid-nineteenth century by Henry T. Schoolcraft who, though still interested in philology, recognized the religious origin of much of the art. Garrick Mallery, at the end of that century, provided the first continental synthesis. Like Schoolcraft, Mallery cited then-available ethnographic data and also acknowledged the art's religious significance.

The combination of the early philological interests and the later ethnographic approaches had an important implication for the history of North American rock art research. The study of much of global rock art can be understood historically as an outgrowth of the discovery and acceptance of the antiquity of western European Upper Paleolithic art. One result was the strong influence that European interpretations had on rock art studies in other regions, particularly hunting magic. North American rock art, in contrast, had its own research tradition prior to the systematic study of the European art. Ironically, the influence of the European hunting magic interpretation on North American rock art interpretation only developed as this explanation was losing favor in that region.

The first "modern" regional synthesis, in the sense of including a systematic data analysis, was provided in 1929 by Julian Steward, an anthropologist who subsequently gained renown for his theory of multilinear evolution and contributions to cultural ecology. Perhaps surprisingly, given his anthropological background, Steward effectively denied any connection between historical tribes and rock art – or maybe this is not surprising in light of his insistence (despite his own evidence) that hunter-gatherer cultures were principally "gastric" in nature. Steward's attitude was perpetuated by many subsequent archaeologists, who accepted on faith the contention that most regional rock art traditions were necessarily prehistoric, not also potentially historical/ethnographic, in age. Perhaps the most influential of these archaeologists were Robert Heizer and Martin Baumhoff (1962) who published a widely read monograph on Great Basin rock art. Among other matters, this introduced hunting magic as the preferred interpretation of hunter-gatherer rock art, at the same time that European Upper Paleolithic archaeologists were rejecting that theory.

Heizer and Baumhoff were, however, traditional cultural-historical archaeologists, and their interest in rock art was not on the agenda of then-developing processual archaeology. A professional rock art research lacuna resulted, with subsequent North American rock art studies, with only occasional exception, the product of amateurs. The most prominent of these was Walt Disney cartoonist Campbell Grant, who championed hunting magic in a prolific, and again influential, series of popular books and articles.

The common processual archaeological dismissal of rock art was ostensibly based on the fact that, at that time, it could not be dated, but the deeper issue was that symbolism and cognition were considered epiphenomenal and, therefore, of little importance in the cultural ecological and materialist paradigm of that period. Significant professional archaeological interest in rock art, accordingly, did not reappear until the late 1970s, promoted by a series of factors. One was then-widespread cultural interests in shamanism and archaeoastronomy and their apparent connections to some hunter-gatherer rock art. Another was renewed attention to ethnographic research, especially in the far west, and the "discovery" of rock art ethnography. Initial attempts at chronometric dating also started at this time. But perhaps the most important variable, in the long-term reemergence of North American rock art research, was the development of heritage management as the primary emphasis of archaeological work. This required the consideration of all aspects of the archaeological record, not just those pertaining to individual research designs, and it involved the consideration of a wide range of heritage values, including specifically art, aesthetics, and, ultimately, Native American religious concerns and issues.

North American rock art research, accordingly, has flourished in the last three decades as the archaeological profession has increasingly reoriented itself towards heritage management. Direct chronometric dating techniques, though sometimes still experimental, have dispelled the contention that the art is entirely undatable. Post-processual archaeology, with its interest in symbolism and interpretation, has provided a theoretical justification for rock art studies. Perhaps most importantly, however, legally mandated Native American involvement with heritage management has pushed sacred sites, including rock art, to the forefront of concern.

Key Issues/Current Debates

As with many global regions, North American archaeology originated when colonialist attitudes about indigenous peoples were prevalent. North American rock art research is no different and, while many archaeologists have moved beyond the primitivist biases that colonialism engendered, colonialist thought remains the subtext of the most significant current debate in North American rock art research (Whitley and Whitley 2012). This concerns ethnography: whether there is directly relevant rock art ethnography in certain regions; what this ethnography implies about origins, functions, and meanings of the art; and the potential relevance of ethnographic accounts to truly

prehistoric rock art corpora. Although seemingly an empirical controversy, the debate is founded on underlying and opposing philosophical positions, with largely unrecognized but significant social implications.

Although commitments on both sides of this debate vary from extreme to moderate, the colonialist position can be generally characterized as denying or downplaying any putative ethnographic data in favor of interpretations based on contemporary western archaeological models and contexts. This partly reflects the belief that a complete or near-complete cultural disjunction exists between the pre- and post-European contact periods. Where ethnographic information is admitted to exist, the statements are considered to be literal and factual comments that can be fully understood in contemporary and rationalist Euro-American intellectual terms. Where such statements make no obvious rationalist sense, in western scientific terms, they are dismissed as evidence of rock art ignorance by indigenous informants, thereby supporting the entirely prehistoric-age interpretation of the art.

The postcolonialist attitude, in contrast, starts with the premise that rock art ethnography may exist in many regions. If found to be present and despite the fact that substantial disruption occurred to indigenous cultures with European contact, specific aspects of these cultures, such as religious beliefs and practices, may not have been entirely destroyed, and precontact indigenous knowledge may have been preserved. Statements of religious belief, from this position, are recognized as inherently counterfactual in nature, with ethnographic data thereby frequently requiring symbolic-metaphoric interpretations, which must be contextualized in terms of relevant indigenous thought systems. Continuity between the ethnographic/historical and more truly prehistoric periods, if any, must be empirically demonstrated on a case-by-case basis, but the passage of time alone is not considered an adequate justification for denying this possibility. (Change occurs over time, but time does not cause change to occur.) Over a century of continuity in ethnographic comments about rock art, in a series of North American regions, has been cited in support of this position and contrasted with the fact that prevailing and opposing, more "purely archaeological" interpretations have consistently changed, on average, every decade.

These two philosophical and methodological positions underpin the current, most visible aspect of North American debate, which concerns the shamanistic interpretation of certain corpora of this art. Some (but not all) North American hunter-gatherer rock art has been interpreted as shamanistic, based on ethnographic and other lines of evidence (including, using independent data and a separate approach to analysis, the neuropsychological model for the forms of the mental imagery of trance; see Lewis-Williams and Dowson 1988). These interpretations have been contested, in some cases vigorously, primarily by simply denying the relevance of the ethnographic data. Alternative explanations have only occasionally been offered in the shamanistic critiques. These commonly emphasize hunting magic. Although there is ethnographic evidence for shamanistic hunting magic rock art in some but not most regions (Keyser and Whitley 2006), the critiques instead follow the colonialist archaeological assumption that dietary concerns were the primary basis for non-Western ritual and belief and that western intellectual models best explain all types of human behavior.

The social implications of these contrasting positions are only occasionally recognized. The colonialist stance reiterates the view that Native Americans do not, and historically did not, have any knowledge of rock art and that the art is therefore necessarily prehistoric, not potentially ethnographic/historical, in age. This effectively separates Native Americans from any direct connection with the archaeological record and serves to strip them of their patrimony. This last fact has particularly important consequences now that Native American tribes have been awarded legal rights to aspects of the archaeological record and are actively attempting to reestablish their claim to their patrimony and heritage. The postcolonialist opinion holds that there is a direct link between contemporary Native Americans and at least the recent prehistoric past. Based on widespread ethnographic evidence, it emphasizes the sacred

nature of rock art sites and acknowledges their importance in terms of social memory, education, and self-identity for tribal peoples. Postcolonial rock art research has served as an effective bridge between archaeologists and Native Americans, whereas the colonialist agenda perpetuates the divide and antagonism that has traditionally existed in North America between the two parties.

Other key current research topics include the gender implications of rock art; the widespread, unusual acoustical properties of many rock art sites; the relationship of rock art sites to the landscape, in both symbolic and adaptive terms; chronometric dating, including the dating of the earliest art; and site management and conservation techniques and approaches. Because of Native American's increasing participation in heritage management, including the prioritization of their heritage values during the planning for site management, research on management and conservation techniques is likely to increase in the future.

International Perspectives

The divergent history of North American rock art research, relative to the remainder of the western (and especially Anglophone) world, initially sets it apart from global research trends. This isolation has continued, to a certain degree, with international practices and interests having only limited impact, although there are two important exceptions to this generalization. The first concerns shamanistic interpretations of hunter-gatherer rock art. Despite debate, ethnographically based shamanistic interpretations of North American rock art had been suggested at least since Mallery in the nineteenth century, and they are currently advocated for specific American regions and corpora by a number of archaeologists. David Lewis-Williams' (e.g., 2012) shamanistic research on South African San (Bushman) rock art has, accordingly, resonated with North American researchers, with a significant methodological and philosophical impact on them, especially concerning the use of ethnographic data. His parallel development of the neuropsychological model for the mental imagery of trance has likewise been influential analytically, though in fact it was inspired by slightly earlier work on Chumash rock art in southern California by Thomas Blackburn. Similarities in the kinds of ethnographic and prehistoric cultures present, and the types of data available for analysis, helped create a natural research bridge between these two geographically distant regions. Furthermore, the emphasis on the origin and meaning of rock art in both of these regions sets them slightly apart from hunter-gatherer rock art research in some other parts of the world, notably Australia, where the primary concern typically is the implications of the art for social processes rather than its symbolism and religious significance.

The second area of research in which North Americanists have heavily participated is rock art chronometrics. In this case, the specialized kinds of expertise and equipment needed to conduct these studies necessarily require international collaboration, with Americanists participating fully in this regard. Although much remains to be done, the first steps towards a chronometric understanding of worldwide rock art have occurred, and North American researchers have played a key role in this regard, both in terms of establishing regional North American chronologies and in the development of the techniques to date rock art globally.

More than research history serves to separate North American rock art studies from international ones, however, specifically with reference to one of the most widely studied problems in archaeology. This is the initial appearance of art and its implications for the beginnings of behavioral-cognitive modernity. There is a consensus that art and modernity developed long before the Americas were colonized, despite the fact that we are still not certain when that event occurred. Regardless of specific date, it seems unlikely that North American research can directly contribute to this central archaeological issue.

Future Directions

North American rock art, despite substantial research and management advances in the last few decades, confronts a series of daunting

challenges. The amount of rock art, especially in the west, is quite high: over 1500 sites are known in California alone, for example, with similar numbers in surrounding states. But very few sites have been fully documented or carefully researched, let alone published. At the most basic level, there is still a substantial amount of foundational work that must be completed before the full range and variability of the continental record is known and before regional rock art chronologies are adequately understood. Fewer still of these sites have been subjected to proper condition assessments; hence, the relative preservational status of North American rock art, including the potential for its long-term sustainability, is all but unknown in any general sense. These circumstances suggest an agenda for future North American rock art research and management. This would include, first, a substantial program of systematic data collection. The recent proliferation of digital recording equipment and techniques, which have increased the accuracy of documentation, facilitated data storage and manipulation, and dramatically improved fieldwork efficiency, enhances but does not guarantee the possibility of achieving this goal.

Continued chronometric research is also seriously needed, second, both in terms of technique development and improvement, and empirical applications. Although some locales have at least preliminary chronometric sequences, such as the Great Basin, Lower Pecos, and northern Plains, almost no chronometric dating has occurred in others (e.g., the Columbia Plateau). Yet this kind of information is crucial not simply to understand the art but also to better integrate it into regional cultural-historical sequences.

Professional site management (including conservation) approaches and applications need to be applied, third, not simply on an ad hoc site-by-site basis, as has occurred to this point, but regionally and collectively. These include professional site documentation, condition assessments, and management plans. Absent these kinds of programs and information, applied on a regional scale, site management will consist of little more than putting out forest fires, thereby remaining cost ineffective and, potentially, futile in terms of the larger resource base. Like the other items on this list, this is a massive and difficult goal to achieve. But the recent development of rapid, quantitative approaches to site condition assessment (Dorn et al. 2008) makes this at least possible, though, again, far from guaranteeing completion.

The future of North American rock art, from this perspective, can be seen optimistically. We now have the tools and abilities to obtain a better understanding of this art and ensure its long-term preservation. But it will be up to this and future generations of the archaeological community to see that the appropriate steps are implemented to fulfill this agenda.

North American Terminal Pleistocene Extinctions: Current Views

J. Tyler Faith
School of Social Science, Archaeology Program, University of Queensland, Brisbane, QLD, Australia

Introduction

The end of the Pleistocene in North America witnessed the extinction of a remarkable array of large mammals, encompassing at least 32 genera of megafauna (animals > 44 kg) and another 4 genera of smaller mammals (Table 1). The majority of extinct genera ($n = 30$), including mammoths and mastodons, saber-toothed cats, and giant ground sloths, became globally extinct at this time, whereas a handful ($n = 6$) disappeared from North America while continuing to survive elsewhere. Altogether, more than 70% of North America's megafaunal genera disappeared (Barnosky et al. 2004). In addition to extinctions at the generic level, several megafaunal species with surviving North American congeners also disappeared near the end of the Pleistocene, including the dire wolf (*Canis dirus*), the American lion (*Panthera atrox*), Harrington's mountain goat (*Oreamnos harringtoni*), and the beautiful armadillo (*Dasypus bellus*).

North America's late Pleistocene extinctions are not only remarkable in terms of the diversity of animals to disappear but they are also noteworthy in that the extinctions primarily affected the larger species (Koch and Barnosky 2006). While it is true that some of the extinct mammals were small in size, such as the Aztlan rabbit (*Aztlanolagus agilis*, ~2 kg) and the diminutive pronghorn *Capromeryx minor* (~10 kg), the majority ranged in size from large to massive. For example, the giant beaver *Castoroides ohioensis* weighed up to 100 kg (compared to

	Tapiridae	*Tapirus*[a]	Tapirs
Artiodactyla	Tayassuidae	*Mylohyus*	Long-nosed peccary
		Platygonus	Flat-headed peccary
	Camelidae	*Camelops*	Yesterday's camel
		Hemiauchenia	Large-headed llama
		Palaeolama	Stout-legged llama
	Cervidae	*Navahoceros*	Mountain deer
		Cervalces	Elk-moose
	Antilocapridae	*Capromeryx*	Diminutive pronghorn
		Tetrameryx	Shuler's pronghorn
		Stockoceros	Pronghorns
	Bovidae	*Saiga*[a]	Saiga
		Euceratherium	Shrub ox
		Bootherium	Harlan's muskox
Proboscidea	Gomphotheriidae	*Cuvieronius*	Cuvier's gomphothere
	Mammutidae	*Mammut*	American mastodon
	Elephantidae	*Mammuthus*	Mammoths

[a]Genus survives outside North America

~20 kg in its living relatives) and the giant ground sloth *Eremotherium*, weighing in at ~3500 kg, was comparable in mass to an African elephant (*Loxodonta africana*). All North American mammal species larger than 1000 kg disappeared, as did more than half of those between 32 and 1000 kg (Koch and Barnosky 2006).

Of the 36 genera to disappear during the late Pleistocene, the last appearances of 16 are securely dated to between 12,000 and 10,000 radiocarbon years ago (all dates discussed here are in radiocarbon years) (Grayson 2007; Faith and Surovell 2009), a time period referred to here as the terminal Pleistocene. The remaining

taxa are quite rare in the fossil record, and most lack reliable last appearance dates altogether, hindering the establishment of a comprehensive extinction chronology. However, statistical analyses of the chronology suggest that all genera may have disappeared during the terminal Pleistocene (Faith and Surovell 2009). The clustering of extinctions at this time coincides with a period of dramatic climate change, which caused massive shifts in the composition and distribution of plant and animal communities, and with the arrival of Clovis hunter-gatherers in North America, which until recently has been considered the earliest secure evidence of people on the continent. These temporal associations play an important role in attempts to explain the extinctions.

Definition

Why did North America's Pleistocene megafauna disappear? For decades archaeologists, paleontologists, and a range of Quaternary scientists have tried to account for the extinctions. Stemming from their chronological correlations with the extinctions, there are two dominant explanations for the losses: climate change and human predation. Understanding their role in the extinctions has been the subject of intense debate that continues today.

Historical Background

Nineteenth-Century Explanations

The historic roots of scientific enquiry into the problem of North America's late Pleistocene extinctions have been traced in great detail by Grayson (1984). The following discussion draws heavily from his work.

Although it is now accepted as fact that extinctions occurred in the past as they do today, the recognition that species could become extinct emerged only during the late eighteenth century. Prior to then, naturalists studying the history of life found the possibility of extinction both unlikely and a direct challenge to the presumed divinity of creation. However, at the very end of the 1700s, owing largely to the work of French naturalist Georges Cuvier, a growing body of fossil evidence demonstrated without question that extinct animals lacking living representatives once inhabited the earth.

With the reality of extinction clearly demonstrated, it did not take long for naturalists to become aware of the magnitude of extinctions in North America. By 1825, ten extinct North American mammals were recognized, including two species of giant ground sloth (*Megalonyx* and *Eremotherium*), two proboscideans (*Mammuthus* and *Mammut*), and several artiodactyls (e.g., *Bootherium* and *Cervalces*), among others. Many naturalists working on the topic, including Charles Darwin, reacted to the growing awareness of the magnitude of North America's extinctions with utter astonishment.

The mounting evidence for massive extinctions in North America and elsewhere posed a scientific problem that demanded explanation. Stemming from the presumption that the extinction of Pleistocene mammals occurred suddenly, extinction scenarios forwarded in the early 1800s included rapid and catastrophic geological change of a sort never before observed in modern times (e.g., global glaciation, flooding on a biblical scale). These catastrophist explanations were rejected by uniformitarians, most notably British geologist Charles Lyell, who, believing the extinctions to have occurred over an extended period of time, argued that slow, natural changes across the surface of the earth were to blame. Although the precise nature of such changes was rarely made explicit, possible mechanisms include gradual changes in the physical environment, such as climate, seasonality, or habitat structure.

Arguments that humans played a role in prehistoric extinctions were initially formulated in the late eighteenth century and became increasingly popular through the 1800s. Prior to the 1850s, however, a crucial stumbling block was that evidence for the contemporaneity of people with extinct megafauna was lacking. At the time, the antiquity of humanity had yet to be

established, and most naturalists, including Cuvier and Lyell, believed that the emergence of people postdated the extinct Pleistocene mammals. This perspective changed during the 1850s, when archaeological research in France and England provided unequivocal stratigraphic evidence that people and extinct Pleistocene megafauna coexisted. For Lyell, who had long recognized the potential impact of humans on modern plant and animal communities, an anthropogenic role in the extinctions seemed the most powerful explanation. Many of his contemporary naturalists soon followed suit, suggesting that humans were solely, or at least partially, responsible for past extinctions on a global scale.

Emergence of the Contemporary Debate

Although the scientific context within which the debate takes place has changed significantly, many contemporary explanations for the extinctions are rooted in those that emerged in the nineteenth century, focusing primarily on the extent to which people or external physical change (e.g., climate change) contributed to the extinctions.

One of the more important factors in the emergence of the modern extinctions debate was the advent of radiocarbon dating. Before then, those interested in the matter could only speculate as to when the extinctions took place, posing obvious challenges when attempting to relate the losses to causal mechanisms. Even with the availability of radiocarbon dating, however, establishing a reliable chronology proved challenging in the past and continues to do so in the present. For example, early attempts (1957–1960) to establish an extinction chronology for North America's megafauna led to the conclusion that the extinctions were Holocene in age, with many species disappearing around 8000 years ago, but some surviving until as recently as 2000 years ago. Such a chronology would be rejected out of hand today.

Making use of the growing list of radiocarbon dates for extinct megafauna, in 1967, Paul Martin published one of the most influential analyses of the extinctions (Martin 1967). Noting that carefully excavated and well-dated Holocene archaeological sites consistently lacked remains of extinct megafauna, Martin truncated the extinction chronology and suggested that the main wave of extinctions occurred around 11,000 years ago. This corresponded precisely with emerging dates for Clovis archaeological sites, which at the time represented the earliest evidence for the peopling of the Americas. As discussed below, Martin believed that this temporal correlation was not coincidental.

Martin (1967) was impressed by the fact that most of the animals lost in North America were large herbivores or the carnivores and scavengers that were ecologically dependent on those herbivores. Large herbivores were potentially attractive prey to Clovis hunters, a premise supported at the time by archaeological associations between Clovis points and mammoth remains. Martin was also struck by the fact that the late Pleistocene extinctions differed from those documented earlier in the Cenozoic in that (1) the ecological niches of extinct forms were not replaced by new or closely related species and (2) there was no appreciable extinctions in the small mammals, reptiles, amphibians, or plants. These factors set the late Pleistocene extinctions apart from presumably climatically driven losses earlier in time. Perhaps most intriguing, not only did human colonization correspond with extinction of the megafauna in North America but a parallel correlation between human colonization and the loss of megafauna also seemed apparent elsewhere (e.g., Australia, New Zealand, and South America). To Martin, the only mechanism capable of accounting for this was human predation. Today, this argument is widely known as the "overkill hypothesis."

Over the years, Martin (1984) refined the details of Pleistocene overkill in North America. He hypothesized that around 11,500 years ago, Clovis hunters entered the continent through an ice-free corridor east of the Canadian Rockies and encountered an abundance of large prey that were naïve to human predators (i.e., lacking adequate defense behaviors). With such an abundant supply of easily captured prey, Clovis hunters rapidly multiplied and spread across the continent. In doing so, they devastated North America's large mammal community and brought about the extinction of the megafauna in a geological instant. This rapid extinction is referred to as the "blitzkrieg" model. To support the plausibility of blitzkrieg, Martin cites evidence for the ecological

devastation and extinctions wrought by humans following the colonization of islands and extrapolates these data to the continental scale.

Although the inferred 11,000 BP extinction wave overlaps with the appearance of Clovis in North America, the end of the Pleistocene is also characterized by dramatic environmental change. Many Quaternary scientists attempted to incorporate such change into explanations for the extinctions. Stemming from observations made in the 1960s that late Pleistocene biotic communities often contained a mixture of northern and southern species – referred to as disharmonious or nonanalog associations – it was suggested that late Pleistocene climates were more equable than those of the Holocene (i.e., less extreme seasonal fluctuations). In short, warmer winters allowed southern forms to expand north and cooler summers allowed northern forms to expand south. In the same year that Martin formulated the overkill hypothesis, Axelrod and Slaughter independently applied this concept to the problem of the extinctions, arguing that increased seasonality at the onset of the Holocene was to blame for the losses.

Since then, numerous additional climatic explanations have been developed to account for the loss of North America's megafauna. Among the more widely cited explanations are those of Graham and Lundelius (1984) and Guthrie (1984). Graham and Lundelius' (1984) coevolutionary disequilibrium hypothesis argues that as climates became less equable at the onset of the Holocene, changes in vegetation structure caused coevolved mammal communities to disassemble, disrupting ecological relationships between plants and animals. For large herbivores, the outcome was reduced niche differentiation and heightened competition for forage, ultimately leading to the extinction of species less adapted to the novel plant communities. Guthrie (1984) proposes that a long and varied growing season during the Pleistocene promoted a diverse, spatially complex vegetation mosaic capable of supporting a wide range of large herbivores. A possible transition to shorter and less varied growing seasons at the onset of the Holocene increased zonation in the plant communities and decreased the quantity and quality of forage available to large herbivores, with extinction following. A more recent, but related, hypothesis argues that rising atmospheric CO_2 concentrations near the end of the Pleistocene lowered plant nutrient content, initiating a series of feedback mechanisms that caused megafaunal populations to crash (Faith 2011).

Key Issues and Current Debates

The debate over the cause of North America's megafaunal extinctions is far from resolved today. Although each scenario advanced to explain the losses has its strengths, one does not have to look far to find weaknesses. Some of the major issues that routinely emerge in the debate are highlighted below.

Pleistocene Overkill

Archaeological Evidence

The fiercest criticism of overkill comes from archaeologists who see little empirical evidence for it. The overkill hypothesis proposes that Clovis people hunted massive quantities of now-extinct megafauna on a continental scale. However, among the 36 genera of large mammals to disappear near the end of the Pleistocene, kill sites have been confidently documented only for mammoth, mastodon, and camel. For the remaining genera of extinct mammals, there is no evidence of human predation whatsoever, causing many to doubt the fundamental premise of overkill.

Martin (1984) responded to this argument by suggesting that the North American extinctions occurred so rapidly in geological time that archaeological evidence of overkill should be very difficult to come by. At the same time, however, proponents of the overkill hypothesis, including Martin, cite the abundance of kill sites for moas in New Zealand as evidence that human predation drove the extinction of these large flightless birds. This contradiction that overkill can lead either to an abundance or scarcity of evidence poses a serious logical challenge to the hypothesis. This challenge appears to have been met in an upcoming paper by Surovell and Grund (2012), who argue that the archaeological signature of overkill can be very different (i.e., many or few kill sites) depending on the temporal depth of the

N

extinctions, human demographics, and taphonomic bias. For now, only time will tell whether the absence of evidence for hunting of extinct North American megafauna is truly evidence of its absence.

Island Extinctions

Is it possible that small populations of hunters armed with Stone Age technology could cause massive extinctions on a continental scale? Among supporters of the overkill hypothesis, the answer is unquestionably yes. To establish that catastrophic anthropogenic extinctions are not only feasible but have happened numerous times in human prehistory, Martin draws upon evidence from island settings. Across the islands of the world, there is unquestionable evidence that extinctions rapidly followed in the footsteps of human colonists. The apparent synchrony between island colonization and extinctions, together with colonization of the Americas and extinctions, contributes to an appealing, albeit disheartening, argument – wherever people went in prehistory, extinctions followed.

The logic behind connecting what happened on islands to what happened on continents has been challenged repeatedly in the literature (e.g., Grayson 2011). Namely, it is well established that island populations are vulnerable to extinction because of their small population size, clearly delineated and often small habitable landmass, and lack of source populations from elsewhere. These factors are not in play at the continental scale. In addition, extinctions on islands are often the result of a combination of factors, including human predation, introduction of alien species (e.g., dogs, pigs, rats), and vegetation change. In no case is it clear that hunting alone drove island extinctions, as required by overkill. In short, the fact that people contributed to island extinctions is largely irrelevant to what happened in North America.

Colonization of the Americas

At the time of the formulation of the overkill hypothesis, Clovis archaeological sites, typically dated to between 11,570 and 10,900 radiocarbon years ago (Meltzer 2004), represented the earliest evidence of people in the Americas. The apparent synchrony between colonization and extinctions supported the rationale behind overkill, especially considering the parallel – although debatable – correlation between island colonization and extinctions. However, there is now compelling evidence that the Americas were colonized well before Clovis. At Monte Verde in southern Chile, some 16,000 km south of the Bering land bridge connecting Asia to North America, there is spectacularly preserved evidence for a pre-Clovis presence in the Americas dating to 12,500 radiocarbon years ago (Dillehay 1997). Moving further north, the Paisley Caves in Oregon provide the oldest evidence for humans in North America, based on human coprolites dated to between 12,260 and 12,400 years ago (Gilbert et al. 2008). There is even evidence that people hunted mastodon prior to Clovis, as indicated by the Manis mastodon from Washington, which dates to 11,960 radiocarbon years ago and was found to have a bone projectile point embedded in its rib (Waters et al. 2011).

It is now clear that people were present in the Americas well before Clovis and that they overlapped with and hunted some of the megafauna for upwards of 2000 years. Given the difficulties in detecting the earliest people or the latest megafauna in North America, this temporal overlap is likely to increase with future field work. This protracted overlap falsifies the strict blitzkrieg model of the extinctions and raises questions concerning the supposed rapidity with which humans are said to have exterminated the megafauna. However, it is impossible to say how much overlap is "too much" to accommodate within an overkill scenario, and there is little reason why humans could not have contributed to the extinctions over extended periods of time.

Extinction Chronology

In order for humans to have hunted North America's Pleistocene megafauna to extinction, those megafauna had to have been present when humans arrived. Of the 36 mammal genera involved, however, only 16 can be shown to have survived to the time of human arrival on the continent (Grayson 2007; Faith and Surovell

2009). Thus, the reason archaeologists have failed to provide substantial evidence for human predation on extinct megafauna could be because the potential prey became extinct long before humans arrived on the scene. For example, there is no evidence that *Aztlanolagus* or *Eremotherium* survived the Last Glacial Maximum.

The possibility of extinctions prior to the terminal Pleistocene poses an obvious problem for the overkill hypothesis. However, those taxa missing from the terminal Pleistocene tend to be poorly represented in the fossil record. This raises the possibility that insufficient sampling is responsible for their absence from the terminal Pleistocene, in which case overkill remains viable. A statistical examination of the radiocarbon chronology of extinctions suggests that this is likely the case (Faith and Surovell 2009). Nevertheless, overkill critics argue that even if this is true, it remains possible that the megafauna had begun to decline long before then (Grayson 2011). For example, experts in the paleobiology of the giant ground sloth *Eremotherium* believe that plummeting winter temperatures at the onset of the Last Glacial Maximum caused its range to contract southward to the point where it was extirpated from North America (McDonald and Lundelius 2009). This is consistent with its fossil history and implies that *Eremotherium* was absent from North America long before it was colonized (the latest *Eremotherium* survived in South America).

The Broader Picture

Although the extinction of the megafauna at the end of the Pleistocene is astounding in its scope, the story does not end there. At the same time that extinctions were taking place, both small mammals and plants were undergoing substantial range shifts. Even a species of spruce tree (*Picea critchfieldii*), which was abundant and widespread in the Lower Mississippi Valley during the Last Glacial Maximum, did not survive the end of the Pleistocene. These changes cannot be explained by human activities but are attributed without issue to climate change. In addition, at least 19 genera of birds disappeared during the late Pleistocene. Some of these, including the massive *Teratornis*, were scavengers whose extinctions were likely tied to the loss of the megafauna. However, others include flamingoes, shelducks, and jays. Their disappearance at the end of the Pleistocene is more difficult to attribute, directly or indirectly, to human predators.

Multiple lines of evidence indicate that the end of the Pleistocene was a tumultuous time for North America's plant and animal communities. At least some of these changes, but perhaps all, cannot be accounted for by people. This simplicity appeals to critics of overkill, since only climate change is capable of explaining the entire suite of biotic changes observed at the end of the Pleistocene. As discussed below, however, climatic arguments are not without their own set of problems.

Climate Change

Although there is good reason to doubt that people played a role in the extinctions, even outspoken critics of the overkill hypothesis readily admit that compelling climatic explanations are lacking (e.g., Grayson 2011). There are many reasons for this, although the simplest is that none have explicitly linked climatic variables to the paleoecology of extinct species, such as dietary habits, habitat preferences, and geographic range, in any persuasive manner. There are several other problems that plague attempts to explain the extinctions by climatic mechanisms, briefly discussed below.

Previous Climate Change

There is no question that the end of the Pleistocene was a time of dramatic climate change on a global scale, with profound impacts on the plant and animal communities of North America. However, dramatic climate changes occurred repeatedly during glacial/interglacial cycles throughout the Quaternary. Yet in North America, massive extinctions are observed only at the end of the Pleistocene. There is no evidence that the magnitude or rapidity of change at this time was any more extreme than during earlier glacial/interglacial cycles, causing many to doubt that climate change adequately explains the extinctions (Barnosky et al. 2004; Koch and Barnosky 2006). For climate change to remain a viable

explanation, it must be demonstrated that climate change at the end of the Pleistocene was somehow unique.

Supporters of climatic explanations note that our understanding of the magnitude and rapidity of climate changes during previous glacial/interglacial cycles is based primarily on isotopic evidence from deep sea or ice cores. Although these data provide insight into global temperatures and continental ice volumes, they provide no insight into variables that may be relevant to the extinctions, including vegetational complexity, seasonality, or duration of the growing season. Of equal importance, global climate records are not a substitute for empirical paleontological and paleobotanical data documenting the response of biotic communities to climate change. In short, scientists do not yet know whether climate change at the end of the Pleistocene was unique or not.

Selectivity of the Extinctions

Compared to earlier episodes of mammal extinctions in North America, the late Pleistocene extinctions are unusual in that the losses disproportionately affected large mammal species. Smaller mammals, which were commonly the victims of climate-driven extinctions earlier in time, fared quite well at the end of the Pleistocene. This pattern lends some support to the argument that people, rather than climate, drove the extinctions, since larger species are presumably preferred prey. Body size alone, however, does not explain the entire situation. Johnson (2002) showed that extinction risk was highest among species with low reproductive rates regardless of body size. Among those species with low reproductive rates that survived, many are arboreal, nocturnal, or prefer to live in densely vegetated habitats. These are precisely the sort of traits that would reduce their possible interaction with human foragers, suggesting that humans did indeed play a role in the extinctions. If climate change alone were to blame for the extinctions, it is very difficult to imagine why it would spare arboreal or nocturnal animals. The selectivity of extinctions has yet to be adequately explained by extinction scenarios relying on climate change.

Empirical Problems

In addition to the issues raised above, some of the more noteworthy attempts to explain the extinctions in terms of climate change (Graham and Lundelius 1984; Guthrie 1984) also suffer from a lack of empirical support. For example, paleobotanical evidence provides no evidence for changes in vegetation complexity of the sort proposed by Guthrie (1984). Likewise, several lines of evidence suggest that late Pleistocene climates were characterized by higher seasonality in both temperature and solar insolation compared to today, in contrast to the predictions of the coevolutionary disequilibrium hypothesis (Graham and Lundelius 1984). While intriguing, these climate hypotheses are not convincing.

International Perspectives

North America was not the only continent to suffer major megafaunal extinctions near the end of the Pleistocene. Across the continents, more than 90 genera of megafauna disappeared within the last 100,000 years or so (Barnosky et al. 2004; Koch and Barnosky 2006). The international perspective on North America's losses is largely colored by debates over the cause of extinctions elsewhere. The case of Australia, which in many ways parallels the North American debate, provides an excellent example.

Many of the empirical challenges that hinder resolution of the debate in North America are also evident in the Australian record. Of ~68 extinct Pleistocene species, there are 25 known to have survived to the late Pleistocene (beginning at 130,000 years ago), of which only 15 are known to overlap with human colonization of the continent ~45,000 years ago. It is unclear whether those species missing from the time of human arrival reflect extinction earlier in time, as argued by advocates of climatic explanations, or instead insufficient sampling of the fossil record, as argued by supporters of anthropogenic extinction scenarios. The empirical evidence for human involvement in the extinctions is particularly weak. Whereas North America has confirmed kill sites for three genera of

megafauna, Australia has none. This is interpreted by some as evidence that people had little to do with the losses, whereas others argue that such evidence is neither expected nor necessary. Sweeping climatic explanations have been proposed, although, as is the case for North America, none are particularly compelling as they do not explicitly link climatic variables to the individual species.

Considering the parallel structure of the debate, the Australian perspective on what happened in North America largely depends on one's viewpoint on the Australian losses. Those favoring anthropogenic extinctions in Australia see the losses in North America as part of a global pattern of colonization followed by massive extinctions (Brook et al. 2007). On the other hand, there are many Quaternary scientists who see very little evidence of this in Australia or in North America (Wroe et al. 2006).

Future Directions

Speculation and debate over the cause of North America's megafaunal extinctions has persisted since the problem was recognized in the nineteenth century. Although continued fieldwork and technological advances have improved the quantity and quality of data available since then, the debate is far from resolved today. There is reason to believe that this is largely due to the manner in which hypotheses are framed (Grayson 2007).

Most attempts to explain the loss of North America's Pleistocene megafauna, whether in terms of human activities or climate change, share the following similarities: they try to account for (1) the loss of all species (2) at the same time (3) by the same mechanism. Such blanket explanations ignore the fact that extinction is an evolutionary process that must be understood at the level of individual species and in terms of their ecology, demography, and biogeographic histories. For example, by proposing that human predation or climate change between 12,000 and 10,000 years ago caused all extinctions, one overlooks the fact that the ground sloth *Eremotherium laurillardi*, which seems to have preferred subtropical to tropical climates, likely retreated into South America long before then (McDonald and Lundelius 2009). This clearly illustrates why it is important to examine the history of individual species when trying to understand what happened to them. An end of the extinctions debate will require future scientists to examine the biogeographic histories of individual species in relation to paleoclimatic, paleoecological, and archaeological data.

North and Saharan Africa: Geography and Chronology

Giuseppina Mutri
Diet and Ancient Technology Laboratory,
Sapienza University of Rome, Rome, Italy

Introduction

Northern Africa is the northernmost region of the African continent, linked by the Sahara to Sub-Saharan Africa and by Egypt to the Sinai Peninsula, which is in Asia. Northern Africa can be divided into four big natural zones: the first is Maghreb that stretches from Tunisia to Morocco along the Mediterranean coast and is

North and Saharan Africa: Geography and Chronology, Fig. 1 Map of North Africa

predominantly mountainous (Fig. 1); the second is the Sahara region, covered by the desert that goes from the Atlantic to the Red Sea; and the third is Sahel, a belt of grasslands and savannas south of the desert. Finally there is the Nile Valley that borders the Sahara desert to the east.

Northern Africa is underlain by folded sedimentary rock and is, geologically, more closely related to Europe than to the rest of the continent of Africa. The Atlas Mountains, which occupy most of the region, are a part of the Alpine mountain system of southern Europe.

The North Africa plateau is formed mostly by a tableland of very ancient rocks, today occupied by the Sahara desert. The internal area of the tableland is broken by some isolated mountain massifs: Ahaggar, Tibesti (where the highest peak in the mountains is Emi Koussi, 3415 m high), and Darfur (where the highest point is mount Marra, 3088 m). This vast region is skirted to the west by a plane that stretches around the estuary of the river Senegal, to the north by Libyan and Tunisian planes, to the northwest by the Atlas Mountains where the highest peaks are the High Atlas and Mount Toubkal (4167 m). Several big rivers flow at the edge of the Sahara; they have a tropical regime with a single high water season in correspondence to the rain season. The Nile, the longest river in the world and in Africa (6671 km), after having crossed Sudan where the waters of the Blue Nile and of the Atbarah River flow into it, enters Egyptian territory through a narrow valley and then flows through a vast plane to the delta that empties into the Mediterranean. Mali and Niger are crossed by the river Niger, while the southwest border of Mauritania is crossed by the Senegal River. Lake Chad is located in the Sahara desert; its size varies because of evaporation and irregular rainfall (Longman 1974).

The overall critical political issues in North Africa determined, in recent years, a reduced quantity of fieldwork and data collections. This situation offered the chance for an interpretative work on data already collected and published in the past. Often this speculative step of the research took advantage of new dating protocols and integrated methodology of study. Crossed sets of data and multidisciplinary approaches opened new perspectives on crucial issues, such as the paleoenvironment during the MIS 5, related to

the Out of Africa theory and about the Mid-Holocene aridification of the Sahara.

A few very interesting interpretative papers came out, which offered new interpretations about paleoclimatic and archaeological aspects of North African prehistory.

In this new edition of the Global Encyclopedia of Archaeology, we will shortly update the information widely discussed before about North African Geography and Chronology (Mutri 2014), showing the state of the art of the geography and prehistoric archaeology of North Africa in a paleoclimatic perspective.

Historical Background

Research in North Africa started in the colonial period and has since then been characterized by a multidisciplinary approach.

Geographical explorations, aimed at better understanding the geography and the geology of the desert areas, were carried out together with ethnographic studies that brought into light the variety of the Berber and Bedouin cultures, their economic systems, the relations between the groups, and the subordination to the dominant Arab culture and to the concept of centralized state.

Archaeological research was also the result of such strong interest in the region.

In Tripolitania and Cyrenaica, the British with McBurney and the Italians with Petrocchi are the protagonists of the discovery and excavation of archaeological sites of great importance (McBurney 1967; Petrocchi 1940).

But the Sahara in particular came to be at the center of the attention of the pioneers of research.

The archaeological exploration of the African continent has developed in parallel with the colonial period.

In the first half of the twentieth century, the archaeological exploration of the Sahara also intensified, especially by French and Italian archaeologists. The discovery of rich rock art (dating from the late Paleolithic to modern times) and Paleolithic and Neolithic sites allowed the reconstruction of the population of the region from the early Paleolithic periods to the present (Fig. 2) (Le Quellec 2008).

Several authors have highlighted the importance of the multidisciplinary studies on North Africa and on the Sahara that have contributed to the understanding of climate change and man's adaptation to it.

Key Issues

Paleoclimate

The study of the climate history registered in the lake sediments in various zones of the Sahara has

North and Saharan Africa: Geography and Chronology, Fig. 2 Rock Art from Tassili

allowed reconstructing the various climatic phases of the Quaternary period. The sediments of the Lake Megafezzan and of the Tunisian Chotts clearly indicate the presence of 17 glacial cycles, interrupted by short humid periods and by interglacial periods. About 10,000 BP, at the time of the Holocene Climate Optimum, the Sahara was covered by a savanna and was rich of vegetation. During this phase the African Monsoon moved north where a series of wetlands consequently formed, making it also possible for men to inhabit the area again (Su and Neelin 2005). The actual hyperarid climate of the Sahara stabilized around 4,000 BP, following a steady process of desiccation that started around 6,000 BP. Around 5,000 BP, the African Monsoon gradually moved south, and this led to the definitive drying up of the area.

From 150,000 to 130,000 BP, Africa experienced colder and more arid condition than the present. Around 130,000 BP, a warm phase moister than the present began, and this lasted until 115,000 BP, with greater rainforest extent and the deserts almost completely covered with vegetation. Subsequent cooling and drying of the climate led to a cold, arid maximum at 70,000 ^{14}C, followed by a slight moderation of climate, and then a second aridity maximum at around 22,000–13,000 ^{14}C. Conditions then quickly became warmer and moister, though with an interruption by aridity around 11,000 ^{14}C. A resumption of warm, moist conditions led up to the Holocene "optimum" of greater rainforest extent and vegetation covering the Sahara. Conditions then became somewhat more arid and similar to the present. Relatively brief arid phases (e.g., 8,200 ^{14}C years ago.) appear to punctuate the generally moister early and Mid-Holocene conditions.

Around 150,000 years ago. There was the maximum of the penultimate glaciation (Oxygen Isotope Stage 6) with generally drier conditions than present and extended desert in North Africa (Van Andel and Tzedakis 1996).

Between 125,000 and 120,000 years ago, there was the moistest phase of the Eemian interglacial (Isotope Stage 5e). Rainforest occupied a far greater area than at present, and rainfall was generally higher over North Africa.

During the period between about 110,000 and 11,000 ^{14}C years ago, there was a great deal of variability in climate across the North African region, though conditions were generally drier and cooler than at present.

The most intensely dry and cool phases across Northern Africa and Arabia are thought to correspond to cold, ice-rafting phases in the North Atlantic.

The period between 90,000 and 110,000 years ago represents the arid phase following the end of the Eemian interglacial. There are indications from the record of desert-dune formation across southwestern Africa that at least part of this phase was extremely arid (Stokes et al. 1997). Desert conditions seem to have existed over a large area west of about 25 deg.E and south of about 18 deg.S.

An intense cold stage occurred between 75,000 and 58,000 (Oxygen Isotope Stage 4). Sea level was about 75 m below the present level, and vegetation conditions seem to have been much as they were at the Last Glacial Maximum (see below), with greater-than-present desert extent in North Africa (Van Andel and Tzedakis 1996).

The Oxygen Isotope Stage 3 period, between 57,000 and 24,000 BP, was characterized by an unstable climate that fluctuated on timespans of a few thousand years (Van Andel and Tzedakis 1996).

Shortly before the Last Glacial Maximum, 28,000–22,000 ^{14}C years ago in North Africa/the Levant, conditions around 28,000–25,000 ^{14}C years ago seem to have been significantly moister than at present, with soils being formed (Goodfriend 1988). This may reflect conditions moister than present across North Africa in general.

The Last Glacial Maximum aridity goes from 22 until 13,000 ^{14}C years ago and may have been a slightly moister phase (though still very arid) separating two extremely arid phases. Aridity and, to a lesser extent, cooling are the major features of Africa during the full glacial period. Ancient sand dune distributions suggest that the Sahara desert zone extended hundreds of kilometers further south than at present, compressing the other vegetation and climate zones equatorward. However, in a restricted area of the northwest Sahara, greater

winter rainfall seems to have given moister conditions, with a belt of semi-desert appearing to the south of the present-day desert margin (Hooghiemstra et al. 1992).

Around 12,500 ^{14}C years ago, there appears to have been a rapid further increase in temperature and in moisture availability throughout most of Africa.

During the Younger Dryas, approximately 10,800–10,200 ^{14}C years ago, a cold, dry period affected Europe, and at the same time, Africa also seems to have experienced a relatively arid phase. In North Africa, for example, the water levels of Lake Chad fell, although Thomas and Thorp (1993) suggest that the climate may not have been much drier than at present. The levels of east African lakes fell during the Younger Dryas (apparently gradually over several hundred years), and there was a reduction in forest pollen in the mountains.

After the Younger Dryas, conditions became moister. The vegetation zones of the Sahara seem to have lain in similar positions to those of the present day (Lézine 1989), although Thomas and Thorp suggest from the level of Lake Chad that conditions were moister than present at around 10,000 ^{14}C years ago.

After 9,000 ^{14}C years ago, conditions in North and Central Africa had become much moister than at present. The Sahara desert had virtually disappeared under a mixture of semiarid and seasonal vegetation types (Lézine 1989; Ritchie 1994).Organic-rich mud layers in the Eastern Mediterranean suggest maximum precipitation and freshwater discharge by the Nile between 9,000 and 8,000 ^{14}C years ago.

Between 8,000 and 7,000 ^{14}C years ago, due to the much greater rainfall, Lake Chad (in the southern Sahara) was greatly expanded in area during all or most of this phase and surrounded by extensive inter-dune wetlands.

The generally northward movement of monsoon rains into the Sahara region can be expected to have resulted in a northward expansion of rainforest as well, and this does appear to be the case from the pollen record (Brooks et al. 2005). A conjectural boundary for the rainforest zone is drawn here.

A severe arid phase (correlated in many places around the world) seems to have affected North Africa around 7,500 ^{14}C years ago (Alley et al. 1997), perhaps lasting for a century or two. There was a reduction in Nile flooding, in NW Sudan lake levels, and at sites in the Western Sahara, the Sahel, and sub-equatorial Africa.

Between 6,500 and 5,000 ^{14}C years ago, conditions across northern, central, and east Africa became somewhat drier than before but were still moister than today. For example, on the basis of pollen and charcoal, Neumann et al. (1995) suggest a mixture of semi-desert and denser scrub and grassland for the Western Sahara, in areas that are now extremely arid. A similar picture is obtained by Ritchie (1994) on the basis of pollen evidence and by Lario et al. (1997) for the Blue Nile on the basis of sedimentological and zoological indicators.

After about 5,000 ^{14}C years ago, lake levels suggest that aridity in North Africa became more severe, culminating in an arid phase about 3,800 ^{14}C years ago, a partway return to moist conditions 4,000–3,000 ^{14}C years ago, and a decline to aridity thereafter (Petit-Maire and Gua 1996).

The extension of the Green Sahara from 130 to 70 ka BP has been revised in a recent paper by Scerri et al. (2014). Using the Biomes from Community System Model elaborated by Hijmans et al. (2005), the authors reclassified the data into ArcGIS, adding new variables such as temperatures and precipitations. The simulated model shows that with an increase of precipitation, the biomes were transformed and a complex paleohydrological network were activated. That elaborated system of lakes and river could have played an important role in the spread of genus *Homo* in North Africa.

Short wet periods were already individualized by Drake et al. (2013) for the timespan between 350 and 20 ka BP, using a combination of OSL dating, GIS, and PDF. The result showed that the spatial distribution of humid sites is compatible with a number of different modern human dispersal theories.

As stated by Nicoll (2016), also spring-fed paleolakes were crucial in modern human dispersal. Data from Bir Tarfawi and Bir Sahara, in

the Western Desert of Egypt, nowadays hyperarid, were re-analyzed after a series of SAR-OSL dates have been collected from the five paleolake phases known in the area (Wendorf et al. 1994).

Except for the last phase, which starts at 41 ka BP and seems to be characterized by an arid to hyperarid climate, the other four paleolake phases show different degrees of water presence. The presence of spring water determinated the formation of favorable biomes outside the usual "Out of Africa" corridors.

Clarke et al. (2016) analyzed the climatic change during the Mid-Holocene in Near East and related area, among which the Western Desert of Egypt was also considered. Combining terrestrial and marine record, the authors individualized two distinct periods of increased aridity, one at the beginning of the fourth millennium BC (3600–3700) and one at the end (3100–3300). From 13,000 to 3500 BP, six main ecological phases of evolution of water basins in Farafra Oasis were recognized (Gallinaro 2008). A moment of environmental and ecological variability was individualized from 6600 and 5200 BP, which indicates a drying trend.

Homination

The first hominid remains found in North Africa is the *Australopithecus bahrelghazali*, found in Chad. The remains is a fragment of jaw found in the valley of Bahr el Ghazal near Koro Toro. This species is dated to between 3.5 and 3.0 million BP and is therefore contemporary *Australopithecus afarensis* (Brunet et al. 1995).

The first evidence of human occupation in North Africa is in the form of the comparatively rare occurrence of very early stone tools. The majority of these Oldowan sites are undated, but the date 1.8 million years proposed for the site of Aïn Hanech in Algeria (Sahnouni et al. 2002) suggests that hominins colonized North Africa at the same time that the first dispersals into Eurasia were taking place. Oldowan sites in the Sahara are extremely rare. Although Oldowan artifacts have been found at several localities, these are rarely in either stratigraphic position or as part of unmixed deflated archaeological assemblages. Four areas appear to have clear evidence for an Oldowan occupation – the Saoura Valley in Algeria, around the Richât Massif in Mauritania, Enneri in Chad, and Fezzan in Libya. Interestingly, there are no well-documented Oldowan sites in Egypt and Nubia (Veermersch 2001), suggesting that the Nile was not a main route of hominin dispersal in the Lower Pleistocene (Mirazon-Lahar 2010).

Around the same period, Acheulean complexes started to appear also in Mediterranean Africa, in Ain Hanech in Algeria or in the Thomas Quarry 1, and in Casablanca in Morocco; on the other hand, sites in Western Africa seem to be rare.

In the Western Desert of Egypt, the Acheulean findings have been studied since the first decades of the past century following the research carried out by G. Caton Thompson and E.W. Gardner in the oasis of Kharga and Dakhla. Other sites have been located in more recent years such as the sites 8715 in Umm Shagir, Arkin 8 in Nubia, the site 8817 in the Dungul oasis, and BS14 in the Bir Sahara depression. The Acheulean sites along the Atbara in Sudan seem to be more recent, while the excavations made in 1949 in Abu Anga near Khartoum by A.J. Arkell allowed to unearth manufacts that were identified as Acheulean sensu lato by F. Wendorf.

North Africa and the Sahara have a rich record of Acheulean sites, a small number of which are dated. The nature of the artifacts and the distribution of the few dates that exist suggest that early Acheulean occupation in the Lower Pleistocene was also very ephemeral – the key locality being the complex of sites at Casablanca, Morocco, where the oldest archaeological industry is an early Acheulean assemblage dated to approximately 1 million years. Late, Middle Pleistocene Mode 2 localities are much more frequent and probably indicate a change in either biogeographic patterns (perhaps associated with the establishment of glacial cyclicity and recurrent wet episodes) or the adaptive scope of hominin groups.

Middle Stone Age and Anatomically Modern Human

The record of the Middle Stone Age/Middle Paleolithic in North Africa and the Sahara is

extremely rich, although the almost complete absence of dated sites makes its interpretation difficult. In Sub-Saharan Africa, the MSA first appears between ~350,000 and 300,000 BP, disappearing in the last 50,000 years. This 300,000-year period encompasses major climatic shifts that would have made the Central Sahara at certain times uninhabitable and at other times part of a rich ecosystem interconnected by rivers and lakes, deeply affecting the biogeographic distribution of hominin populations. The period also encompasses major evolutionary events, in particular the first evidence of modern humans in East Africa around 200,000 BP, as well as of their first dispersal out of Africa in the subsequent wet interglacial phase 130,000 to 100,000 BP. The beginning of this dispersal is archaeologically difficult to identify, as the stone tools manufactured by early humans did not differ substantially from those produced by other hominins since ~ 300,000 BP (including the Neanderthals). However, once established in North Africa, these early humans developed a new cultural identity, the Aterian, which has distinctive stone tools. The Aterian has been dated in Morocco from 110,000 to at least 80,000 BP (Barton et al. 2009) (Fig. 3). However, the extremely arid conditions that prevailed in the Central Sahara between 70,000 and 14,000 BP probably restricted the temporal extent of the Aterian occupation in the region.

A series of fossils seems to confirm the African origin of the anatomical modern human *Homo sapiens*, the most famous being the Jebel Irhoud fossil, related to a MSA technology as Musterian and/or Aterian. Some of the more ancient fossils are related to Acheulean technocomplexes.

The most important element that indicated an early development of a modern behavior as regards the production and spreading of iconic symbols can be found in the Blombos cave in the South African Republic. Two small ochre fragments flattened by scraping and then engraved were found in the Middle Stone Age levels and were dated to over 75,000 BP with the thermoluminescence method.

Late Stone Age and Out of Africa

Late Stone Age defines the technological complexes and cultures that developed in Africa in the last phases of the Pleistocene that clearly presents innovative features compared to the previous phases. In this period in the whole African continent, blade industries are developed by *Homo sapiens*, and microlithic characteristics also become more marked. This phenomenon took place at different times in the different regions, and this underlines the role played by the environment in the decision-making process of the groups of humans.

Before hominins could disperse out of Africa, they needed to disperse out of their likely area of endemism in Sub-Saharan Africa to North Africa, the most likely departure point for Eurasia. Prior to the Middle Pleistocene, successful long-term colonizations of North Africa by hominins were very rare and apparently less successful than their colonizations of Eurasia. The Early Pleistocene hominin dispersal into Eurasia was most probably along the western coast of the Red Sea. The ability of hominins to successfully disperse into Eurasia and successfully colonize northern continents was made possible by the ecological and climatic diversity within Africa (Lahar 2010) (Figs. 4 and 5).

International Perspective

The migration of *Homo sapiens* out of the African continent is currently one of the most debated topics in the scientific debate. Many scholars support the *Out of Africa* model rather than the others (replacements, assimilations, multiregional models (Aiello 1993). Probably modern humans used many ways to leave Africa, and multiple dispersal events, according to many scholars, are the most probable explanation to their exit (Garcea 2010; Gunz et al. 2009), even if the Levantine corridor may still be considered as the main route of human dispersal during the MIS 5e -125-120 ka BP (Smith 2010).

Shea (2003) recognized two main episodes in the Out of Africa 2 model, the first one from 130 and 80 ka BP and the other one after 50 ka BP.

North and Saharan Africa: Geography and Chronology, Fig. 3 Aterian peduncolate

If the makers of Aterian and Taramsa lithic complexes were the protagonists of the first episode (Garcea 2010), after 50 ka BP, *Homo sapiens* from the African Mediterranean coasts have definitely replaced Neanderthals in the Levant.

During the Pleistocene the occupation of the Sahara, an area far from the Mediterranean coast and from the Nile Valley, was determined by the availability of water. The most critical period is the Late Pleistocene that corresponds to the Late Stone Age phase. The present state of research in fact seems to indicate an interval between the last Aterian traces that date to 60 ka and the scarcity of LSA occupations (30,000). The areas close to the

N

North and Saharan Africa: Geography and Chronology, Fig. 4 LSA. Chronology and palaeoclimatology of Jebel Gharbi

coastline present a different situation: despite a time interval between the emergence of the two cultures, these cover a shorter timespan that goes from 40,000 to 24,000 BP.

The last phases of the occupation of the Sahara can be referred to the Holocene, after 10,000 BP, when the arid and hyperarid areas were again covered by vegetation and inhabited by animal species. There is evidence that in the same period, domestic livestock appeared in Eastern Sahara and then probably spread West around 7,000 BP.

The spreading of the microlithic industries in the Sahara zone and more in general in North Africa took place over a long period of time. The phenomena of the reduction of tools and the backing of the edges take place for the first time with the Iberomaurusian culture (>20,000 BP) and are well documented by the important sequences in

North and Saharan Africa: Geography and Chronology, Fig. 5 Hafted geometric tool

the sites of Tamar Hat, Taforalt, and Haua Fteah. Examples of what has been called the "programmatic use of the environment" have been traced working on some famous sites in the Nile Valley, such as Wadi Kubbaniya and Shabona. A. Testart has emphasized the different adaptation patterns followed by the hunter-gatherer cultures and the coexistence of sedentary and mobile groups with a variety of intermediate patterns, a variety of techno-economic specializations, storing methods, and social organizations (Testart 1982).

Around 12,000–10,000 BP, there was a peak in humidity, precipitations exceeded evaporation, and the rainfalls probably occurred at regular intervals (Vernet 1995). From then on, adaptation in the Sahara regions took place in more diverse and complex ways, indicating a higher degree of interaction between man and the surrounding environment. In the Western Desert of Egypt, the sequences of the sites of Nabta and Bir Kiseiba indicate that occupation there started at the end of the arid phase. Bir Kiseiba was inhabited again for the first time in the period called el-Adam that goes from 10,000 to 8,200 BP. The site is important because remains of oxen were found there (dating to 10,220 to 9,460 BP) and were considered domestic by A. Gautier (1984). Although this hypothesis was opposed for some time, it was however very important in re-framing the problems related to the Neolithic production in the Sahara. The oases of Selima, Siwa, Farafra, Dakhla, and Kharga provide more evidence of humid conditions in the early antico Holocene.

The most ancient traces of human presence in the southern area of the Nile Valley are to be found in the remains of the Lower Paleolithic (pre-Chellean, Chellean, Acheulean, Micoquian) and Middle Paleolithic (Mousterian) industries, unearthed in fluvial terraces that date to the Middle and Late Pleistocene (600,000–90,000 BC).

Lithic industries became stylistically very diverse in the Lower Pleistocene (20,000–8,000 BC); traces of both macrolithic and microlithic industries have been found in the valley, defined as Epi-Levalloisian because of the Levallois stone knapping\flaking technique typical of the Middle Paleolithic, and microlithic blade industries, often characterized by an intensive use of scrapers. Both these industries seem to be of Nilotic origin and would thus indicate the presence of indigenous populations with different cultural traditions in the same area. They could represent a paleo-African tradition typical of northeast Africa. The Epi-Levalloisian industries include the Halfan (about 18,000–15,000 BC) between the second cataract and Kom Ombo, the Edfuan (about 15,800–15,000 BC) in the region of Esna, the Sebilian (about 13,000–9,000 BC) between the second cataract and Qena, and the Afian (about 12,000 BC) in the region of Kom Ombo. The blade industries include the Fakhurian (about 16,000–15,600 BC) in the region of Esna, the Menchian (about 13,000–9,000 BC) in the area of Kom Ombo, the Isnian (about 11,000–10,500 BC) in Esna (Esna), the Sebekian (about 14,000–11,600 BC), and the Silsilian (about 13,000 BC) in Kom Ombo. The remains of fauna associated to these industries clearly indicate the exploitation of the river resources with activities such as fishing, hippopotamus hunting, gathering of freshwater molluscs, and \or hunting of wild livestock in the nearby savannas. The sites are generally small in dimension and seem to suggest camps that were used seasonally by groups of 5–40 individuals.

However the presence of millstones and grinders in the Menchian and Isnian sites suggests that these groups also gathered wild grasses and consequently that they were preadapted to the preparation of food.

There is no certain evidence that blade industries derived directly from the Middle Stone Age industries in Northern Africa. Even the Dabban present in Libya between 40,000 and 20,000 BP seems to be a result of influences from the Cyrenaica (like the more ancient pre-Aurignacian). Until the end of the Middle Stone Age, changes occurred at a slow pace. The Dabban also asserted itself as a lasting and stable tradition, and only after 18,000 BP did a series of changes take place more rapidly and in shorter time, both in the Nile Valley and in the Maghreb territories.

An increased regional diversification, which characterizes the Late Pleistocene, could be the consequence of a higher population density and the symptom of specific forms of a more differentiated adaptation. Moreover, the technological specialization of the period indicates a more efficient exploitation of resources. The indirect percussion with punch technique in fact allowed to manufacture more efficient tools.

The Iberomaurusian and the Caspian are the two main cultures of the North African Late Stone Age. The first spread along the coast and inland toward the wet area of Tell from Eastern Morocco to the Gulf of Tunis, between 20,000 and 10,000 BP. Iberomaurusian was first classified by J. Roche (1963); later J. Tixier (1963) designed a system that was adopted as typological model for all the North African Late Stone Age \Epipaleolithic industries, devised by analyzing the various deposits in the Maghreb region. It is known that this definition was given at the beginning of the last century in a context in which North African studies tended to view the archaeological and industrial aspects in relation to a specific historic-geographic dimension. Today, on the contrary, the tendency is to have a general view of the Late Pleistocene technology in all of Northern Africa (including the Nile Valley), which represents the preliminary step to food production.

The Mechta el-Arbi human type (or Mechta-Afalou) is considered the prototype of the anatomically modern North African man. Remains were found in the numerous Iberomaurusian necropolises. A similar type, called Mechtoid, was found in cemeteries that are present in fewer number than the necropolises (better known are Gebel Sahaba and Tushka) in the Nile Valley (Wendorf et al. 1989.) The Capsian physical type tends to be more fragile than the Mechta el-Arbi; it has a long and slim face and small mandibles. The Capsian were called proto-Mediterranean by G. Camps, thus implying a connection with the actual Berbers (Camps 1982). The Capsian culture attracted the attention of researchers for a long time. Today less importance is given to this culture that in fact lasted for a shorter time than what was believed and occupied a smaller portion of the territory. It is considered to have developed between the Pleistocene and the Holocene, prevalently during the last phase. Geographically its expansion was limited to Tunisia and to the north province of Algeria. It lasted approximately from 11,000 to 8,000 BP. To a certain degree, the Capsian industry can be considered a transitional industry that flourished at the end of the Iberomaurusian. It is a Pleistocene industry characterized by an advanced degree of technological ability, ceramics, and food production (Lubell and Sheppard 1997; Barich and Conati Barbaro 2003). Probably some Capsian groups, which were already sedentary and had developed intensive gathering strategies, helped in the diffusion of new techniques for resource exploitation that had originated outside Maghreb and that spread in the VIII and VII millennium BP. It can be said that this Late Stone Age/Epipaleolithic complex brought on the progressive shift to the pastoral economy in Maghreb, the so-called Neolithic-of-Capsian tradition.

The classification of the Late Stone Age microlithic industries in the Nile Valley is complex, in particular with regard to the industries that flourished between 19,000 and 10,000 BP.

The most ancient industries that can be defined as late Paleolithic are in the area of Wadi Halfa. While the Khormusian is still part of the Levallois tradition, the Halfan in Lower Nubia and the Kubbaniyan in Upper Egypt between 19,000 and 17,000 BP are characterized by important

microlithic features such as microblades and microflakes and by a recurrent Ouchtata presence in the Kubbaniyan. Both cultures practiced hunting in the savanna, game and large-size animal hunting, but also fishing in the river Nile. The high number of grindstones found in the various complexes suggests also that they were gatherers of tubers and wild grasses. The use of the tuber and of a very common plant in the habitat of the Nile (*Cyperus rotundus*) is well documented in the Wadi Kubbaniya site, where many examples of a complex use of the environment in ancient periods can be found. The exploitation of big quantities of fish and wild plants indicates treatment and storage systems that allowed to keep resources and consume them at a later time. This is a strongly innovative aspect that indicates a major change that occurred in the habits that had been of immediate consumption in the case of simple gatherers.

The Late Stone Age Nilotic industries reveal elaborations and complex processes of differentiation that occurred from 16,000 BP especially in Upper Egypt. The main industries can be dated to the Lower Paleolithic alluvial phase in which the size of the river Nile grew smaller because of a reduced flow of water from the springs. This however did not affect human occupation that is on the contrary attested to be consistent by several large sites and by the contemporary development of differentiated economic activities. Around 12,000 BP, a crisis caused by the onset of an arid period determined the spread of intensive gathering in order to integrate the protein diet, though there is no evidence of stable settlements at the time. On the contrary the crisis determined an increase in fishing activities that lasted for a long period. The Elkab site in Upper Egypt that dates to around 8,000 BP is emblematic: here a settlement of hunters and fishermen was occupied for a brief period by humans that developed a highly microlithic industry, where the main components are backed bladelets. Despite the lack of evidence of food production, it is reasonable to believe that the Nilotic groups in the final phases of the Pleistocene were preadapted to animal breeding and controlled wild herd animals like cattle and gazelles. Here however animal breeding, mainly of sheep and goats from the Near East, started around 6,500 BP (5,000 cal. BC) together with the cultivation of barley and wheat, also from the Near East.

Food Production

The most ancient agricultural society known to us in the Nile Valley (and in all of North Africa) is located in the Fayyum depression, in Lower Egypt. Between 8,000 and 7,000 BP, this area was inhabited by sedentary hunters and fishermen (Fayyum B/Qarunian) that made use of microlithic tools and bone harpoons in a context in which the traditional Epipaleolithic economy was still dominant (Figs. 6 and 7). Around 6,800 BP, the first food-producing groups settled in the Fayyum area (Fayyum A/Fayyumian. The characteristics of this culture, i.e., the establishment of sedentary settlements, cereal preservation systems, and fully domesticated resources to dispose of, make the Nilotic Fayyum A culture the real precursor of the settlements of the later Predynastic period.

Northeast Africa offers a series of essential data for the study of the origin of the first types of herding systems, from the beginning of the Holocene in the Western Desert of Egypt, where domestication first started and then spread to the rest of the African territories, to the west, toward the Central Sahara, and to the east in the Nile Valley. With concern to this aspect, and also with regard to incipient cultivation practices, recent studies have sufficiently brought to light the important role this territory and the other Egyptian oasis played (especially Farafra, Dakhla, and Kharga) as autonomous areas for important proto-Neolithic developments and as areas of innovation that connected the Sahara to the Nile Valley (Barich 2002) (Fig. 8).

The Neolithic el-Nabta type (between 8,100 and 7,900 BP) saw the recolonization of the Nabta-Kiseika region at the end of a period of extreme aridity followed by a new humid phase. In this period regular rainfalls provided the conditions for a more stable settlement and for the emergence of a permanent village, the Nabta E-75-6, which is similar to Ti-n-Torha East in Tadrart Acacus, Libya. Wild cereals (sorghum and millet) have been found in recent excavations of F. Wendorf and R. Schild in Lower Nubia and in the Upper Nile.

This research has allowed to identify two main phases of the alluvial deposit during the Late Pleistocene. In Wadi Kubbaniya the sediments of the late Paleolithic deposit have been identified at around 12 m above the actual level of the *wadi* bed and date to between 20,000 and 12,400 BP. In this period the river was less active because of the arid climate, vegetation grew scarce at the source of the river,

and the consequent colluviation in the banks and the great mass of detritus being transported determined a rapid growth of the alluvial plane of the Nile (Wendorf et al. 1989).

The issue concerning the local domestication of cattle that started with the first wild *Bos primigenius* type has been long debated in African studies. In the area of Bir Kiseiba, more than 10,000 faunal remains, mostly species that were adapted to arid climate (hares and gazelles), were found. Some remains of oxen, in an extremely fragmented state, were classified, with a high degree of uncertainty, as domestic remains, or in an incipient state of domestication (Gautier 1984). It was observed that wild examples of Bovidae (oxen or buffalo) could in no way have survived in a climate with such a low humidity level. Presently the new study of the microcondial DNA of

N

the *Bos* type has revealed an ancient separation (that occurred about 25,000 BP) between the African heads and the Eurasian and Indian ones, thus confirming the hypothesis that the African bovine domestication process occurred independently (Holl 1998). This process seems to have taken place in the first phase of the Holocene, at a time in which the monsoon cycle stabilized and summer rainfalls appeared again. Groups that came from the Nile Valley (probably belonging to the Qadian culture) reoccupied the territory that had previously been hyperarid for thousands of years. The possession of small domestic herds made the occupation of desert lands easier, providing an important source of protein during the recurring climate crisis. This hypothesis also explains the rapid spread of livestock in the Central Sahara communities. The arid interval observed in the Sahara sequences between 7,900 and 7,700 BP must be considered in relation to the coeval increase of the first experiments in livestock herding carried out by the groups that inhabited the Central and Western Sahara territories (Barich 2002).

Data about the Holocene communities in the Central Sahara has been classified into two categories. The most impressive collection documents the cave art repertoire, carved or painted on the walls of rock shelters in Tassili n'Ajjer, in Tadrart Acacus, in Messak, and in Ahaggar (Sansoni and Emmanuel 1994; Muzzolini 1995; Mori 1998). This region played a key role in the transfer of domestic livestock from Eastern Sahara toward the regions in the south and west. More precise indications about the later phase of the development of Saharan pastoralism have emerged thanks to research carried out in Acacus (Cremaschi and Di Lernia 1998) that shows a diffusion of sites from Erg Uan Kasa to Tanezzuft, between 5,000 and 4,000 BP.

In Niger the first evidence of a pastoral economy dates to the middle of the VII millennium BP and is to be found in the sites of Dogomboulo and Rocher Toubeau and especially in the sites of Adrar Bous. The Tenerian is the pastoral culture par excellence; this culture reached its peak around 5,000 BP and was particularly widespread along the eastern edges of the Air, between the Adrar Bous and Areschima (Roset 1987). The economy of this pastoral group was based on herding, hunting, and extensive wild grain gathering. The studies by F. Paris on Neolithic and post-Neolithic burials in the region of Adrar Bous provide original data regarding the composition of the expansion of settlements during the Late Holocene (Paris 1996, 1997). During the period that goes from the middle of the V millennium to the middle of the IV millennium BP, a number of groups immigrated to this region; these groups had a structured social organization that might also have included é*lites* that built burial monuments and were different from the local group-types from a paleoanthropological point of view. Paris asks where these new populations came from. Because the burial monuments were mostly for men, he suggests that they were intended for prominent people such as the heads of the group and that the organization was of an aristocratic type similar to a chiefdom. The Tenerian culture ended around 3,800 BP, when the climate conditions worsened.

In the coast regions west of North Africa, the traits of the material culture that are commonly called Neolithic (ceramics, polished stone tools, arrow heads worked on both sides) are to be found only in a very restricted area opposite Gibraltar in Northern Morocco (in the territories of el-Khril near Tangier). As regards the bovine and caprovine remains associated in these sites to the Cardial style pottery, Camps (1982) noted that: "It would seem that in this area the introduction of domesticated animals coincided with the beginning of the pottery production."

In Haua Fteah the phase F, documented by the levels VIII–VII (from 6,800 to 4,800 BP – 5,000 to 2,700 BC), was attributed by C.B.M. McBurney (1967), the first archaeologist to work on the site, to the sphere of the Neolithic of Libyco-Capsian Tradition. Mostly caprovine remains were found in Haua Fteah (the presence of bovines is not certain). The caprovines are small in size, especially if compared to the Libyco-Capsian type (levels X–IX). This change seems to have occurred suddenly and non-gradually: E.S. Higgs (author of the zooarchaeological study) concluded that goats

had been imported at a more advanced stage of domestication.

More important information regarding the pastoral organization in these Northern regions come from the Capéletti cave (Khanguet Si Mohammed Tahar) in the Aures Mountains of eastern Algeria (Roubet 1979). The cave is at about 1,500 m above the sea level and shows an uninterrupted stratigraphic sequence caused by a very slow sedimentation process that took place over a period of about 2000 years in the Mid-Holocene (from 6,530 to 4,300 BP). The most ancient phase of occupation (from 6,530 to 5,900 BP) shows no presence of domestic livestock. Later (in the second period) the cave was inhabited by shepherds that made use of Capsian type tools; also tools that consisted in a ceramic piece with a cone-shaped bottom and manufacts in polished stone were found, sometimes decorated and carved. Because of the similarities with the Capsian, the culture was called Neolithic-of-Capsian tradition. The groups of humans exploited a wide range of resources, though this did not include small-size livestock: land and freshwater molluscs, great quantities of various wild plants (Fig. 9). The men were mammal hunters, especially antelopes and gazelles, and of avifauna. The available data seem to indicate a system of transhumance between the plane, occupied in winter, and the plateau, occupied during the summer (Holl 1998). The dimensions of the Capélletti cave suggest that it was inhabited by specialized groups (task groups) of young men that lead the livestock to pasture.

There is a clear chronological *décalage* in the distribution of the pasture lands outside the areas described up to now, both in the Saharan territories and in Sub-Saharan Africa. It is known that the presence of the tsetse fly that infested the southern regions was an impediment (though also cultural factors may have played an important role). The data available does not provide any evidence of domestic livestock on the northwest borders of the Sahara, in the area situated in the Algerian and Moroccan regions of Atlas and Aures, to the north, and in Tanezrouft in the south, along the border between Mali and Algeria. This area seems to have been inhabited by mobile groups of hunter-gatherers (culture of Hassi el-Abiod, culture of Kobadi). Considering this evidence it is correct to say that the northwest portion of the Sahara did not function as a corridor for the passage of domestic livestock from North (Aures) to West Africa. On the contrary the first pasture sites that date to 6,000–5,000 BP (like the famous Adrar Bous in Niger) are located along the western edges of the Ténéré from where probably they spread south and southwest, toward the Atlantic coast of Western Sahara in Tintan and Chami, the Taoudenni basin at Erg i-in-Sâkâne in the Adrar des Ifoghas, the Tilemsi Valley in Mali, Dhar Tichitt in Mauritania, Azawagh Valley in Niger, reaching Kintampo and Ntereso in Ghana.

From the "nucleus" in Eastern Sahara, the pastoral communities rapidly migrated toward the Central Sahara, then return toward the Nile then Sudan, and from here continue toward southern regions. The migration paths are marked by typical settlements, hearths, megalithic burial structures, vast pottery deposits, and burial and ceremonial monuments. In Eastern Sahara the routes intersected in the area between the Egyptian oasis and the Nile. Together with the core-farming activity, agricultural activities, involving imported plant species, were also important in the Nile Valley.

The occupation of the region reached a peak in the Holocene period. The expression *Saharan Neolithic* (also identified as *Sharo-Sudanese Neolithic* by G. Camps) refers to a spectrum of cultural traits that emerged between 10,000 and 5,000 BP in the central area of the Sahara, between 15′ and 25′ N. Lat. Among the innovative aspects that characterize these cultures (that include a series of technological traits, artistic aspects, and settlement patterns), the production of pottery and food preparation, in the context of a pastoral economy, are no doubt the most important elements.

With regard to cultivation processes, the only available evidence indicates the use of species of the millet and sorghum group.

The beginning of the transformation in living habits in the Sahara region coincided with the

North and Saharan Africa: Geography and Chronology, Fig. 9 Proto-Neolithic developments and as areas of innovation that connected the Sahara to the Nile Valley

onset of rainfalls and with the consequent reoccupation of the territoriesthat had been practically abandoned during the arid phase that reached its peak around 20,000. In the transition phase between the Pleistocene and the Holocene, the types of culture that developed were based on

the exploitation of water resources that determined a lifestyle that the archaeologist J.E.G. Sutton defined as "water culture." At first this definition was criticized by many; today it is considered appropriate.

The most reliable sequences in Egypt, Libya, and Niger date the first occupations of the Sahara to the period in which the monsoon cycle stabilized again in the earliest phase of the Holocene. The Nabta and Bir Kiseiba sequences, in the Western Desert of Egypt, begin at the end of the long arid period that followed the Aterian humid period.

The first occupation at Bir Kiseiba (called el-Adam phase, between 10,000 and 8,200 BP) is important because it is where the remains of oxen were found (dated between 10,220 and 9,460 BP) in the E-79-8 site. The el-Nabta Neolithic type (between 8,100 and 7,900 BP) is characterized by the recolonization of the region at the end of a phase of extreme aridity that was followed by the onset of a new humid phase.

During this period more regular rainfalls allowed more stable settlements and the establishment of a permanent village, Nabta E-75-6, which is similar to Ti-n-Torha East in the Acacus area, Libya. Many comparisons have been made between the lithic industry found in the E-75-6 site and the industries of other sites in the western part of the desert, like Wadi Bakht in Gilf el-Kebir, Abu Ballas, and Lobo opposite the Great Sand Sea, the Masara B horizon from Dakhla, and the Early Holocene horizon in Farafra.

In Libya the sequence of the main occupation has been identified in the Tadrart Acacus mountains that, together with the Algerian massif Tassili n'Ajjer, constitutes the most important cave art complex in the Sahara. In the Wadi Ti-n-Torha (Barich 1987), Ti-n-Torha East appears to be a real proto-village with a series of hut bases close to the rocky sides of the *wādī*. The types of fauna indicate an economy based on hunting, fishing, and gathering. It is worth mentioning some very baldy preserved remains of a large-sized bovine (that date to between 8,500 and 8,000 BP). Gautier suggested the remains were of a domestic ox, a hypothesis that was not confirmed by the research carried out later. The stratigraphic series that are visible in the three Wadi Ti-n-Torha sites (East Shelter, the Two Caves site, and the North Shelter) covers the whole period of the Early Holocene.

The sequence at Niger also displays a series of stratigraphic and chronological similarities with the situation in Libya. The research carried out by J. Desmond Clark in Wadi Greboun and in Adrar Bousfu identified an Epipaleolithic culture (Kiffian) in the 1980s; more research by J.P. Roset brought into light sights that date to around the same period: Temet 1 (between 9,650 and 9,450 BP), Ti-n-Ouaffadene (9,360–9,080 BP), and Adrar Bous 10 (9,220–8,840 BP). The lithic complexes are of an Epipaleolithic type, though they also display a rich pottery tradition. On the whole it has been observed that there is a large chronological gap between the first remains of what is believed to be domestic oxen in the Western Desert and the remains found in other regions, such as Saharan and North African. In Niger the sites of Dogomboulo (between 7,100 and 6,600) and Rocher Toubeau (5,650–5,500 BP) are the first examples of an occupation that dates to the Mid-Holocene based primarily on farming. The lithic complex of this horizon (Tenerian) is characterized by large bifacial tools such as gouges, discs, arrow heads, and polished axes. An almost complete skeleton of a domestic ox (*Bos taurus*) found at Agorass n'Tast was dated to between 6,250 and 5,250 BP.

In the area of Uan Muhuggiag, the presence of domestic oxen from the VIII millennium BP is certain although the fauna of the region included also many wild species. In the period between 6,000 and 5,000 BP, the pastoral culture spread to all of the Central Sahara region.

The description of the Neolithic of Sudanese tradition given by A.J. Arkell was based on the similarities between decorative motifs, the wavy line motif, and the dotted wavy line motif that can be found both in the Sahara and in Sudan. Arkell dated the Khartoum Mesolithic, the most ancient, to around 8,000 BP. Today it is believed that the economic transition in Sudan should be considered in connection to the arrival of groups from other regions that brought with them domestic species. The region of Nabta Playa, in the north, has been indicated as one of the places from where these domestic species arrived after having crossed the Nile Valley.

At the beginning of the Holocene (around 8,000–5,000 BC), Upper Egypt was occupied by populations with lithic industries of local Late Pleistocene tradition. They are the Tarifian (about 8,000–6,000 BC) in Thebes, Elkabian (about 6,500–5,000 BC) in the region of Elkab, and Qarunian, initially defined Fayyum B (about 6,100–5,200 BC), in the Fayyum depression. The Elkabian and the Qarunian are associated with a number of remains of fish that confirm an intensive exploitation of water resources.

The so-called Early Khartoum Mesolithic culture, originally thought to have been confined to the areas surrounding the Nile, seems to have spread widely in semi-desert areas. There were therefore two residential zones, between the Nile and the mountains: the area by the river, inhabited during the arid season, between October and June, and the area inland, inhabited during the rainy seasons, in summer. The two areas were equipped with sites for functional and seasonal specialization, hunting stations installed on the peaks of the many *gebels*, within an 8 km radius around the inhabited sites. These have been identified as living quarters because of the deposits found in very thick stratifications. The presence of many burial sites is an indication of the custom of burying the dead inside the village, by the entrance of the huts.

The sites of this early phase are dated in Central Sudan to between 8,000 and 6,500 BP (Caneva 1983; Caneva et al. 1993). They are all characterized by the presence of the earliest type of Sudanese ceramics, pottery items of various sizes, generally large, globular shaped, made with a fine and well-baked clay, with a lithic filler and a surface decorated by impression or engraving. The most significant ornamental motif that is present on more than 20% of the items is the wavy line combed motif, which gives the name to this culture and constitutes the distinctive trait of the Sudanese culture if compared to the coeval Saharan.

The horizon that followed, the Late Mesolithic dotted wavy line pottery, is defined by the sudden appearance of a more uniform pottery production, characterized by a more fragile consistence and a less sophisticated baking process and by decorations obtained solely by impression with combs that create a wolf tooth motif, often dotted wavy lines. The appearance of this type of pottery dates to 6,100 BP like the other type and has the same stratigraphic position as the wavy line pottery, in all the sites were it has been observed, like Shaqadud (Marks and Mohammed-Ali 1991) and Kabbashi (Caneva et al. 1993). The groups that produced it, hunters, as in the first culture, occupy the same area by the river and the same inland territories, though in a less intense and articulated way, and for a shorter period of time. The simultaneous appearance of a uniform pottery, identical to the one of the Central Sahara and of the regions confining with Chad, suggests that the groups of hunters that gradually migrated toward the Nile Valley came from these regions.

^{14}C dating, all around 6,100 BP, indicates that this development took place in a very short time. The pastoral groups, dated to between 5,800 and 5,500 BP, which came from the same Saharan regions, only arrived in the Nile Valley 200 years later. Domestic animals were certainly imported into Sudan from northwest African regions. The characteristics of the first cultures with an economy based on production in Sudan are the same as the Saharan ones, though they seem to have undergone an *itinerant* process, in the course of a slower migration process, which was probably more divided and fragmented compared to the first culture, having been carried out by several groups at different times. From this moment a continuous development toward nomadic pastoralism can be traced in Sudan.

Researches in the Western Desert carried out in the last 20 years by R. Kuper (1989) have shown that the desert was crossed more than inhabited and that the majority of sites identified date to later periods, post-Neolithic, in particular to the type called Halbmond-Leiterband because of its characteristic pottery decorations (4000 BP).

State of Knowledge and Current Debates

North and Saharan Africa: Geomorphology and Climatic History

North and Saharan Africa constitute a vast geographical region delineated by the Mediterranean Sea to the north, the Red Sea to the east, and the Atlantic Ocean to the west. The Sahara desert sands are bordered to the south by the Sahel savannah grasslands, a shifting transitional ecoregion in perpetual expansion and contraction

under the impulse of cyclical climate change. Presently, North Africa partly or wholly embraces Morocco, Algeria, Tunisia, Libya, and Egypt, while Saharan Africa includes the northerly sectors of Mauritania, Mali, Niger, Chad, and Sudan. The most striking geomorphological feature of this region is, of course, the Sahara desert, a vast platform punctuated by high plateaus and mountain ranges whose foundations are composed of Precambrian era rocks. This ancient platform was warped up, denuded, and eroded over time into swells and basins. Sandstone and limestone deposits were accumulated after global warming during the Cretaceous Period that caused huge areas of the Sahara to be submerged. Organic oceanic sediments amassed during this period were transformed into the petroleum and natural gas deposits that are currently exploited by countries like Libya, Algeria, and Nigeria. Over the following millennia, extensive and recurring erosion stripped sediments of the organic nutrients needed for agriculture but maintained their component mineral deposits (bauxite, salt, manganese, iron, gold, copper, uranium). This wealth of natural resources spurred the development of geological research and surveying in the Sahara desert. Explorations for natural resources have indirectly contributed to the growing awareness of this region's prehistory by tracing its geological and geomorphological past and by providing a framework for the understanding of the appearance and evolution of human life in this expansive territory (Fig. 1).

Today, the Sahara represents a variety of landscapes bordered by coastal areas comprising the majority of the population. Inland, the topography

North and Saharan Africa: Geography and Culture During the Lower Stone Age, Fig. 1 Satellite image showing the countries presently included in North and Saharan Africa

N

is relatively monotonous, punctuated by sandy deserts, ridges and basins, and mountains and valleys. The land ascends gradually from the western Atlantic shoreline to form vast plains, and the northerly Atlas Mountain range culminates at Mount Toubkal at an altitude exceeding 4,000 m. Long, profound valleys cut into the plains that extend southward from the Atlas Mountains, reaching into the Algerian Desert regions. Southern Algeria's Hoggar Mountains (3,000 m) and the Emi Koussi volcano (3,500 m) in northern Chad's Tibesti massif are among the most important elevations of today's Sahara. Occasionally, oases with their associated vegetation break with the general aridity of the desert. The mythical great Nile River marks the overall landscape as it flows northward out of Ethiopia, through Sudan and into Egypt, where its huge delta spews fresh water into the Mediterranean Sea. Remarkable expanses of desert surround this vital water source. Other massive expanses of sand deserts are those of Algeria's Great Erg and Libya's Fezzan basin. The central regions of the Sahara, from southern Algeria to western Sudan, are characterized by barren plateaus and hills with a mean altitude of 180–365 m (Fig. 2).

Throughout the Quaternary Period (c. 2.5 Mya), the Sahara offered diverse climatic

North and Saharan Africa: Geography and Culture During the Lower Stone Age, Fig. 2 Present-day desert landscapes from western Morocco – near the junction between Morocco, Algeria, and Mauritania. Sparsely wooded, savannah-like landscape (*above*). Denuded and eroded primary rock surface (*below*) (Photos Jordi Mestre, IPHES, Spain)

scenarios that culminated in a variety of landscapes, including tropical and savannah-like environments well suited to a broad spectra of large and small mammals, including hominins. At the onset of the Quaternary, intense rainfall severely eroded the highlands, redepositing masses of sediment and developing important water systems and alluvial terraces. These waterways constitute the single most important element permitting early humans to occupy and settle the northerly sectors of the African continent. Lakeside regions developed providing ideal settings for human life, and river valleys constituted passageways permitting populations to disperse into new territories. Looking at the Sahara desert today – one of the most inhospitable places on earth – it is difficult to imagine that it once provided a flourishing environment favorable to human life. In fact, desertification of the region began only some 4–5 Kya, when shifts in the earth's axis caused temperatures to increase and precipitation to decrease. From that time, the area suffered the transformation of its tropical plant life into savannah grasslands that finally culminated in the installation of desert conditions.

Much of North African Quaternary climatic history has been interpreted by comparing its geomorphological and stratigraphical associations with evidence from the European Mediterranean coastal areas, notably some well-dated sequences from Italy, France, and Spain. A well-established sequence of fossil shorelines has been proposed especially for the Atlantic facade of Casablanca, as well as in other regions of Morocco and Algeria. Correlations have also been established using paleoclimatic data obtained from deep-sea cores or pollen and vegetation sequences. In North and Saharan Africa, as elsewhere, cyclical climatic change characterizes the Quaternary Period, and its glacial/interglacial dynamics caused variations in pluviosity, marine transgressions, and regressions, as well as in isostatic phenomenon. The most significant effect of climate change influencing the spread of early humans into this zone was certainly the periodic extension of the Sahara desert (Aouraghe 2006). Landscape settings shifted throughout the Pleistocene from dryer, desert conditions to tropical savanna with sparse forest containing Mediterranean essences. These settings provided the ecological conditions necessary to harbor a wide variety of large mammals, many of which were of Afro-tropical origin. Although it is likely that hominins formed a part of migratory waves of animals moving out from similar landscapes to the south and to the east at specific times throughout the Quaternary, there is a paucity of evidence of human activity in this area during the Lower Stone Age.

Many of the large mammals sustained in the region from the Late Pliocene into the Upper Pleistocene underwent slight or no anatomical change and therefore present little biochronological significance. The earliest Pleistocene, characterized by a general lowering in temperatures and increased aridity, is distinguished by open landscapes populated with large, grazing herbivores. Temperatures and pluviosity augmented from around 1.2 Mya, favoring the establishment of extensive water systems and their corresponding forest environments. From around 0.9 Mya, temperatures decreased, degrading landscapes and provoking important changes in corresponding faunal associations. The beginning of the Middle Pleistocene, from 0.78 Mya, is marked by the return of higher temperatures, while the Upper Pleistocene, from around 0.12 Mya, was considerably colder and dryer (Agustí et al. 2009).

Except for intense research in the Atlantic coastal region of Morocco (the Casablanca cave sequence) and in Algeria (Ternifine, Ain Hanech, Ain Boucherit), North and Saharan Africa have been neglected in terms of Early Paleolithic research, especially when compared to East and South Africa. But recent findings have highlighted their importance as a source of knowledge about our shared, distant past. The once widely accepted hypothesis postulating a unique emergence for humanity – east of the great African Rift Valley (*East Side Story*, Kortlandt 1972; Coppens 1994) – has been under question since 1993, when fossil hominins dating to 3.6 Mya were discovered nearly 2,500 km west of the Rift Valley, near Koro Toro in Chad (Brunet et al. 1995). The finds were attributed to a new species of australopithecine named *Australopithecus bahrelghazali*, commonly referred to as

"Abel." Just a few years later, in 2001, new fossils were brought to light in the Chadian, Djurab Desert belonging to a bipedal hominin nearly 7 Myrs old. These hominin remains, denominated *Sahelanthropus tchadensis* or "Toumaï," were also recognized as belonging to a new species and are thought to represent one of the earliest human ancestors, perhaps the closest yet to the chimpanzee-*Homo* divergence. These important discoveries have established Saharan Africa as a key zone for the emergence, evolution, and diffusion of ancient hominins.

Europe and Africa have been separated by the Mediterranean Sea ever since the Atlantic Ocean breached the landmass joining these two continents over 5 Mya. This natural barrier favored evolutionary divergence of humans and other species on either side of the divide, but it did not entirely impede their passage from one to the other throughout the different phases of the Quaternary Period. Although relatively little is known of the timing and mechanisms through which such migrations occurred, growing evidence of a hominin presence in Eurasia from the Early Pleistocene underlines the key role played by the northerly regions of Africa. This region constitutes an obvious geographical crossroads, a sort of greenhouse where favorable conditions encouraged the growth of human culture and socialization that would eventually enable them to establish the demographic success necessary for their spread into Eurasia.

Pioneering archaeological and geological research began in North Africa during the late nineteenth century, notably along the northern Atlantic coastline near Casablanca, revealing evidence of a long succession of human cultures in the area. Except for some precise dating carried out on the Casablanca sequences (OSL, U/Th, ESR, Raynal et al. 2010), the specific geomorphological history of the region has not proven particularly favorable for radiometric dating techniques. Overall, difficulties in obtaining reliable radiometrical dates for artifact-yielding sediments of North African sites have impeded establishing a chronostratigraphical framework within which to place the archaeological finds. Unlike in the East African Rift Valley, North Africa has undergone modest volcanic activity during the Quaternary – its sedimentological record does not offer the same context of successive layers of datable tuff and/or volcanic ash separating neatly stratified deposits. Nor has the region known comparable tectonic activity that, in the East African Rift Valley, exposed the huge stratified sequences that provide a virtually uninterrupted record of fossil-bearing sedimentary sequences for the entire Plio-Pleistocene. Well-preserved fossils and artifacts within datable, sequential volcanic deposits have made East Africa an ideal ground for spectacular discoveries in a well-calibrated chronological framework. Extensively documented research carried out in the Rift Valley since the 1970s, for example, in the Hadar, Afar regions, Omo Valley, Koobi Fora, and Olduvai Gorge (Ethiopia, Kenya, Tanzania), provides a foundation with which to compare North African faunal, hominin, and lithic discoveries, helping to establish their own chrono-cultural evolutionary trajectory. The difficulties in elaborating this framework have steered systematic archaeological research away from the earliest phases of the Paleolithic in the Sahara and Maghreb regions and toward the more recent periods such as the Neolithic and the Bronze Age.

Early Pleistocene (Gelasian Stage, 2.588–1.806 Mya)

Pre-Acheulian/Oldowan/Mode 1

The earliest cultural manifestations of the Lower Stone Age are referred to as *pre-Acheulian*, *Oldowan*, or *Mode 1*. These denominations, corresponding to the *variability* phase of human cultural evolution (Carbonell et al. 2009, 2016), are poorly documented throughout North and Saharan Africa. In contrast, elsewhere on the continent, notably along the East African Rift Valley, discoveries are multiplying, and the age of the earliest stone tool assemblages has been pushed back to 2.6 Mya (Semaw et al. 1997) or older (Harmand et al. 2015). So far, the oldest stone assemblages are known only from this part of the globe and are characterized by worked cobbles and nonmodified flakes. In Africa, the period covered by the cultural umbrella most often referred

to as the "Oldowan" is situated between c. 2.5 and 1.7 Mya. From around 2 Mya, stone industries tend to increase in technological variability, and some assemblages include polyhedrons and/or spheroids.

Following discoveries in East Africa, *Homo habilis* was commonly accepted to be the author of the first stone tool industries. But other hominins, such as robust and gracile australopithecines, are also present at some sites during the same time frame. These hominins have been found in possible or probable association with cut-marked bones and/or knapped stone industries (Leakey 1971; Howell et al. 1987; Sussman 1991; Kimbel et al. 1997; de Heinzelin et al. 1999; Kuman and Clark 2000; McPherron et al. 2010). While the evidence for australopithecines and early *Homo* and their stone industries dating to this time frame is comparatively abundant in South and East Africa, not a single hominin fossil attributed to this period has yet been discovered in North or Saharan Africa. In the future, exploring the earliest phases of hominin expansion into this region will be essential to understanding how they survived and proliferated in the face of the changing paleoenvironmental conditions of the Quaternary Period. North and Saharan Africa certainly holds unexploited information fundamental to understanding the key phases of early human morphological evolution and how stone technologies allowed them to develop culturally and socially, eventually favoring their demographic spread into other regions of the globe.

Migrations of other species from South and East Africa into North and Saharan Africa are documented at the paleontological site of Ahl al Oughlam, a quarry located at Casablanca (Morocco) and dated to 2.5 Mya (Raynal et al. 1990; Geraads 2006). This site has yielded a rich collection of large fossil vertebrates, including tropical species such as elephants, giraffes, rhinoceros, horses, Hippotraginae, and Tragelaphinae, as well as numerous amphibians, reptiles, and birds. In spite of the wide variety of large and small vertebrates found there (over 60), no evidence of a human presence has yet been identified.

The warmer and wetter climatic conditions from around 1.8 Mya resulted in the development of important river systems that crisscrossed the region, depositing thick alluvial deposits. Resulting lakes and marshes provided favorable conditions for a lush, forested environment rich in biological diversity. To date, Algeria boasts the only two excavated sites so far attributed to this period: Aïn Hanech and El Kherba (Sahnouni and de Heinzelin 1998; Sahnouni 2005, 2006; Sahnouni et al. 2002, 2010). These two open-air sites are located in floodplain deposits at the edge of the eastern sector of the Algerian high plateau (Sétif Province). They have yielded a rich faunal assemblage in association with stone tools, knapped from local limestone and flint. The assemblages include cores, sub-spheroids, spheroids, flakes, and retouched pieces. Because of their low degree of formal standardization, their lack of handaxes or cleavers, and the presence of spheroids and orthogonal flaking, these industries are attributed to the Oldowan techno-complex. The age of the sites has been evaluated using paleomagnetic and biochronological criteria to between 1.95 and 1.77 Mya (Sahnouni et al. 2002). Paleoenvironmental conditions assessed for this time frame from faunal remains and radiocarbon isotopes confirm the dominance of an open, grassy landscape with sparse woodlands and indicate a progressive increase in aridity over time (Sahnouni et al. 2010). Species of biochronological interest include *Kolpochoerus heseloni*, *Dicerorhinus africanus*, and *Anancus* (Sahnouni and van der Made 2009) (Fig. 3).

Elsewhere in Algeria, few other Oldowan occurrences are well documented. The El Mansourah open-air site, for example, has yielded Oldowan industries analogous to those from Aïn Hanech, without handaxes and cleavers. The faunal assemblage shows similarities to Aïn Hanech, but some species may indicate that the site is slightly older (Chaid-Saoudi et al. 2006). However, further research is required in order to establish the relationship between the stone industries and the faunal remains. The faunal list includes *Kolpochoerus*, a suid indicative of the Lower Pleistocene. The bovid *Tragelaphus* cf. *gaudryi* predates the *Tragelaphus algericus* from the Early to Middle Pleistocene site of Ternifine. The presence of *Hippopotamus* and *Reduncini* indicates a nearby water source.

North and Saharan Africa: Geography and Culture During the Lower Stone Age, Fig. 3 Typical Oldowan tools from El Kherba and Ain Hanech in Algeria, 1.8 Mya. *Left*: (**a**) and (**b**) are from El Kherba (Redrawn by de Heinzelin); (**c**) is from Aïn Hanech (Drawn by de Heinzelin). *Right*: (**a**), (**b**), and (**c**) are from Aïn Hanech (Redrawn by de Heinzelin); (**d**) is from Aïn Hanech (Drawn by Wilkerson) (Sahnouni and de Heinzelin 1998)

Throughout the rest of North and Saharan Africa, additional evidence for the presence of human populations producing Oldowan-type industries is sparsely documented, and as we have noted, systematic research for the earliest phases of hominin evolution needs to be developed further. In Libya, for example, there have been spot finds of Oldowan tools (worked cobbles) and Acheulian tools (handaxes, cleavers), but they lack precise chronostratigraphical information. The same is true of Egypt, where only isolated finds have been cited (Vermeersch et al. 1990). The situation is similar for the more southerly regions of Saharan Africa, in Mauritania, Mali, Niger, Chad, and Sudan, where there is a paucity of excavated sites and/or spot finds attesting to the presence of early hominins. While to date there have been no finds of early *Homo* dating to this time frame, discoveries of Oldowan tools attest nonetheless to their presence in North and Saharan Africa very early on, establishing the region as a foothold for understanding the subsequent emergence of ever more numerous prehistoric civilizations, both inside and outside of Africa.

Early–Middle Pleistocene (Calabrian Stage, 1.806–0.781 Mys, to Ionian Stage, 0.126–0.781 Mys)

Acheulian/Mode 2

During the *Acheulian* or *Mode 2*, the evidence for stone industries belonging to the *diversity* and *multiplicity* phases of human cultural evolution (Carbonell et al. 2009, 2016) becomes relatively more abundant throughout North and Saharan Africa. Cutting tools such as handaxes, cleavers,

and picks, shaped on large flakes (L > 10 cm, Sharon 2009, and references therein), are emblematic of this new phase of human technological know-how. Throughout the Acheulian, stone knapping was often performed using bifacial technology to extract flakes from disc-shaped cores. Small retouched toolkits appear and develop extensively to include several varieties of converging scrapers (pointed tools). In Africa, the emergence of Acheulian technology is generally believed to coincide with the appearance of *Homo erectus/Homo ergaster*. Behavioral changes accompanying the acquisition of new and advanced technological skills are perceivable in the archaeological record. Higher group mobility, increased social complexity, and organized hunting practices are among the observed achievements.

To date, the oldest known Acheulian industries have been discovered in Kenya, at Kokiselei 4, and in Ethiopia, at Konso-Gardula, dating, to around 1.75 Mya (Lepre et al. 2011; Beyene et al. 2013). By around 1.5 Mya, Acheulian sites became increasingly numerous in South and East Africa (Leakey 1971; Piperno and Bulgarelli-Piperno 1974; Isaac and Harris 1978; Texier 1995; de la Torre 2011). The increase in the number of sites as well as in individual site densities points to adaptive success linked with newly acquired techno-social skills. Sites with continuous stratigraphical sequences covering this time range, such as Olduvai Gorge or Melka Kunturé, bear witness to the generalization of this transition. Acheulian industries are present on the continent up to around 0.3 Mya when they are progressively supplanted by the Middle Stone Age (MSA) industrial complex.

Nascent Acheulian culture (*diversity* phase, Carbonell et al. 2009, 2016) in Africa thus coincides with the installation of the more humid climatic conditions characterizing the beginning of the Calabrian or the earliest Lower Pleistocene (c. 1.7 Mya). Human expansions outside of Africa apparently coinciding with this new cultural phenomenon took place within the context of the more arid conditions of the second half of the Early Pleistocene (c. 1.6–1.4 Mya, Ubeidiya, Israel, Bar-Yosef and Goren-Inbar 1993; Agustí et al. 2009). This second phase is marked by human demographic growth and the progress and complexification of Acheulian-producing populations inside and outside of Africa. The shift in climatic conditions also spurred a new wave of faunal migrations, with the arrival in North Africa of new species of east African origin, such as *Connochaetes*, *Theropithecus*, and *Elephas atlanticus* (Aouraghe 2006).

Acheulian industries and/or *Homo erectus* fossils are documented just prior to the onset of the Middle Pleistocene, at least 1 Mya in North and Saharan Africa. Nevertheless, the paucity of organized research programs in the region explains why much of the material has been recovered only from isolated finds without chronostratigraphical context. Distinctive features of early Acheulian industries in North and Saharan Africa include the mastery of large flake production from giant cores using technologies specifically developed for the production of blanks for large cutting tools (such as bifacial, sliced slab, Kombewa, Victoria West, cobble opening flake or *éclat entame*, Tabelbala-Tachenghit, or Levallois; Tixier 1956; Biberson 1961; Balout et al. 1967; Alimen 1978; Sharon 2009), a range of retouched tools, and the widespread use of discoid knapping technology for flake production. On a wider scale, analogous characteristics are observed in lithic assemblages from the Iberian Peninsula and restricted areas of southern France, India, and the Levant (Santonja and Villa 2006; Sharon and Barsky 2016; Bourguignon et al. 2016; Pappu et al. 2011; Goren-Inbar et al. 2000). Comparatively, looking eastward at the Engel Ela-Ramud basin (Eritrea), important lithic assemblages have been found, sometimes associated with fauna of Oldowan, Acheulian, Middle, and Late Stone Ages (Martínez-Navarro et al. 2016).

Apart from the very large size of some of the stone implements, another distinctive – and intriguing – feature of the North and Saharan African Acheulian is the sheer density of LCTs present in some areas. The existence of huge surfaces literally "paved" with handaxes and cleavers poses important problems of interpretation of these occurrences. It seems plausible that vast areas of North and Saharan Africa where such

North and Saharan Africa: Geography and Culture During the Lower Stone Age, Fig. 4 Accumulation of Acheulian tools in place at Yeslem II (*left*). Large-sized cleaver from Yeslem II (*right*) (Adrar Region, Mauritania, De Lumley et al. 2006)

accumulations have been cited constitute zones of frequentation by hominin groups over thousands of years, probably connected with waterways. The combination of high occupation frequency and very slow sedimentation could help to explain the abundance of stone tools found in some cases (Fig. 4).

Given problems related to obtaining precise chronological information for many of the finds, attempts were made early on to create a chronological framework based on the overall morphology of LCTs, particularly handaxes and cleavers (Tixier 1956; Biberson 1961, 1967). In general, the more thoroughly knapped and symmetrical pieces were thought to be more recent than more partially or less "finely" worked pieces. However, research has since revealed that the concept of a progressive morphological symmetry observable over time is not a valid chrono-cultural notion. On the contrary, some Acheulian sites with long stratigraphical sequences demonstrate that handaxes morphology sometimes shows an inverse tendency, with the more elaborate tools representative of the older levels and the more partially manufactured pieces exhumed from the more recent levels (in Syria, e.g., at Nadaouiyeh I; Le Tensorer et al. 1993, or in France, at the Caune de l'Arago, Barsky and de Lumley 2010). Today, other factors are known to influence the overall morphology of stone tool industries, such as raw material quality and availability as well as differences in site function (as in the Acheulian sequences of Atapuerca's Gran Dolina and Galería, Ollé et al. 2013).

Major Acheulian Occurrences in Chronostratigraphical Context

The earliest and best documented evidence of Acheulian culture in North and Saharan Africa is from the Casablanca sequence in Atlantic Morocco. Situated on a plateau (or meseta) of northwestern Morocco, between the Atlantic coastline and the Middle Atlas Mountain range, Casablanca is well known for its exceptional stratigraphical sequences covering nearly 6 Myrs of geological and archaeological history. The huge sections composing these formations were fortuitously exposed after extensive quarrying was carried out to accommodate Casablanca's expanding urban context. The thick deposits are characterized by a series of barrier beaches of marine and eolian origin, disposed parallel to the present-day shoreline (Fig. 5). Formed by the gradual uplifting of the Moroccan coastline, the age of each of the

North and Saharan Africa: Geography and Culture During the Lower Stone Age, Fig. 5 View of the Miocene, Pliocene, and Pleistocene sedimentary sequence in the region of Casablanca in Atlantic, Morocco. The sections exposed by quarrying provide an exceptional sedimentary record covering nearly 6 Myrs. A number of archaeological cave and open-air sites dating to the Early and Middle Pleistocene were discovered and excavated here since the early nineteenth century. These sites constitute the best known reference for the appearance of *Homo erectus* in North Africa and the development of Acheulian culture (After Raynal et al. 2010). q^{3-4} ,Upper Pleistocene and Holocene; q^2, Middle Pleistocene; q^1, Lower Pleistocene; p, Pliocene; m^6, Miocene (Messinian). Sites illustrated: Thomas Quarry (Thomas I, III, Oulad Hamida 1); AAO, Ahl Al Oughlam; BF, Bir Feghloul; DBA, Bar Bou Azza; DBC, Dar Bouchaïb Oulad Caïla; DM, Douar Mouhak; GBH, Ghandour Ben Habib; Li, Lissasfa; OQJ, Oulad Aj J'mel; OH, Oulad Hamida; OM, Oulad Malik; RBA, Reddad Ben Ali; SAR, Sidi Abderrahmane Quarries; SM, Sidi Messaoud (Raynal et al. 2010)

stepped, dune-covered beaches increases progressively as one moves inland. The successive phases of marine and continental deposition exposed by quarrying in the sections near Casablanca provide a unique opportunity to observe the paleo-littoral context of the region and its evolution over time. They continue to provide a solid foundation for the establishment of the chronostratigraphical framework, for the Maghreb, and beyond.

Since explorations and research were initiated in the first quarter of the last century, the Casablanca depositional sequence has been the object of intense research aiming to understand the mechanics of its formation and to establish a chronostratigraphical framework within which to place its important archaeological occurrences (Neuville and Ruhlmann 1941; Lecointre 1952; Dresch et al. 1952; Biberson 1961; Lefèvre and Raynal 2002 and references therein). Early excavations carried out at Sidi Abderrahmane (Schneider Quarry) revealed for the first time the great antiquity of the human presence on the Moroccan coastline (Neuville and Ruhlmann 1941), attracting early on the attention of eminent prehistorians like Abbé H. Breuil (Institut de Paléontologie Humaine, Paris). Progressively, exploitation of the quarry was to disclose the existence of other cavities containing

archaeological material (*Rhinocéros, grotte de l'Éléphant, grotte de la Gazelle, grotte du Cheval, Cap Chatelier*). Even though the area was classed as a cultural heritage site in 1951, it has been poorly protected, and the degradation of the relationships between quarry workers and archaeologists eventually led to the partial destruction of the sites and unfortunate losses of many of the artifacts.

Biberson exhumed the first remains of *Homo erectus* in 1955 from the *Grotte des Littorines*, including a fragmentary mandible, in association with Acheulian tools and abundant Upper-Middle Pleistocene faunal remains. The human bones were promptly attributed to a new species: *Atlanthropus mauritanicus*. Following a period of neglect lasting nearly 20 years, new excavations were finally undertaken in 1978 thanks to the initiative of the *Service de l'Archéologie du Ministère des Affaires Culturelles du Royaume du Maroc* and then under the direction of the *Institut National des Sciences de l'Archéologie et du Patrimoine* in collaboration with French researchers. The excavations undertaken in the 1950s by Biberson gave rise to the first typological lexicon defining primitive stone industries. This work provided one of the first foundations for a synthetic chrono-cultural framework alongside the widespread lexicon defined by Mary Leakey, based on her monumental work on the lithics from Olduvai Gorge (Leakey 1971).

Today, multidisciplinary research continues to work toward the realization of a coherent correlative synthesis between regional stratigraphy and global glacio-eustatic events in order to precisely evaluate the age of the artifact-yielding deposits of the Casablanca sequence (Texier et al. 1994, 2002; Lefèvre and Raynal 2002). A joint project between France and Morocco has undertaken systematic explorations of the region since 1988 (Raynal and Texier 1989). Different methods have been applied in attempts to establish a reliable chronology (U/Th radiometrical dating, parallelisms with the well-calibrated northern Mediterranean littoral formations and glacial deposits, biochronological criteria such as the succession of foraminifera fauna documented in deep-sea cores). Some of the correlations are based on research carried out in central Italy (Ambrosetti et al. 1972) where a chronological framework has been elaborated according to parallelisms prepared between alternating periods of sedimentation and erosion and marine glacial oscillations by the intermediary of faunal and floral evolution (Fig. 5).

The earliest evidence for hominin activity from the Casablanca sequence comes from the Thomas-Oulad Hamida Quarries complex Unit L and Hominid Cave at Thomas Quarry 1, dating to the end of the Early Pleistocene. Other key archaeological sites identified around the Sidi Abderrahmane locality belong mostly to the Upper-Middle Pleistocene and are representative of the final phases of the Acheulian or the beginning of the MSA (Upper Pleistocene): Bears Cave, Cap Chatelier, Rhino Cave at Oulad Hamida Quarry 1, Sidi Abderrahmane Extension, and Sidi Al Khadir open-air sites.

The age of the hominin-bearing archaeological Level L at Thomas Quarry 1 is evaluated to around 1 Mya (Raynal and Texier 1989; Raynal et al. 2002, 2009), making it the oldest archaeological site with hominin remains in all of North and Saharan Africa. Following systematic investigations at this site, carried out by P. Biberson (1961), a hemimandible of a robust hominin was unearthed in 1969 by P. Beriro and attributed in the same year to *Atlanthropus mauritanicus*. This attribution was based on finds discovered at Ternifine (Algeria) by C. Arambourg in the 1950s (Arambourg 1957; Ennouchi 1969). More recently, these fossils were denominated *Homo rhodesiensis* (Hublin 2001). The early hominins present at Casablanca are generally recognized to be within the variability of robust *Homo erectus* such as those from the Chinese site of Zhoukoudian or from Java, in Indonesia. Between 1994 and 2009, more human remains were exhumed from Thomas Quarry Hominid Cave, including a child's hemimandible, vertebra in anatomical connection, and isolated teeth, found in association with Acheulian tools and faunal remains (Raynal et al. 2010).

The rich faunal assemblage from Thomas Quarry 1 includes *Hippopotamus amphibius* s.1, *Equus mauritanicus*, *Ceratotherium simum*, elephants, *Gazella atlantica*, *Connochaetes*

taurinus, *Ursus* sp., *Crocuta crocuta*, and *Theropithecus* cf. *atlanticus* translating an open, savannah grassland environment with sparse wooded areas (Geraads 1980, 2002; Geraads et al. 1980). Unfortunately, most of the species provide little biochronological information, and they persist in (North) Africa up to the end of the Middle Pleistocene. However, the presence of a third molar from the suid *Kolpochoerus* and the characteristics of the micromammalian assemblage both confirm an Early Pleistocene age for this site (Geraads et al. 1986).

The stone industries (Raynal and Texier 1989; Raynal et al. 2010), ascribed the *Early Acheulian*, were knapped from quartzite cobbles and blocks and flint nodules collected nearby. They include some handaxes, cleavers, and picks on large flakes or cobbles, as well as worked cobbles and cores. Knapping technology was unifacial unidirectional or discoid. Some flakes were produced from polyhedrons. There are also some retouched tools.

Rhinoceros Cave, situated in the Oulad Hamida 1 Quarry, yielded Acheulian stone tools and numerous large vertebrate fossils, among which the white rhinoceros is particularly well represented. The faunal assemblage seems to indicate an open, relatively arid environment. The age of the accumulation is evaluated to around 0.4 Mya (by ESR on tooth enamel).

As a whole, the Casablanca complex provides essential information concerning the appearance of *Homo erectus* in the North African regional context and their evolution toward *Homo sapiens* in an area of the globe where no intermediary fossils (*Homo neanderthalensis*, *Homo heidelbergensis*) have yet been brought to light. Furthermore, the Casablanca sequence, covering around 800 Kyrs of early human cultural evolution, offers a precious database for understanding the variability of Acheulian culture over time. The data so exceptionally preserved and brought to light at this locality is essential for understanding the scenario of early human migrations into Eurasia throughout the different periods of the Early and Middle Pleistocene (Fig. 6).

Fragmented skull parts found in 1933 near Rabat and the Salé cranium (0.4 Mya) found in

North and Saharan Africa: Geography and Culture During the Lower Stone Age, Fig. 6 *Left*: *Homo mauritanicus* mandible from Thomas Quarry 1, Casablanca (Morocco). *Right*: Retouched tool and hand axe emblematic of Acheulian culture – both from Thomas Quarry 1 (Raynal et al. 2010)

1971 show features reminiscent of *Homo erectus* but also display some more advanced characteristics evoking a local evolution to *Homo sapiens*.

In sum, evidence from the Atlantic coast of Morocco indicates the presence of Acheulian-producing populations from around OIS 17 to 5, thanks to a few key, hominin-yielding sites (Sidi Abderrahmane, Thomas Quarry, Oulad Hamida, Rabat, Salé), allowing to postulate that the transition from *Homo erectus* to *Homo sapiens* occurred in this region between around 0.4 and 0.2 Mya (Aouraghe 2006) in agreement with new discoveries at Jebel Irhoud (Hublin et al. 2017). This hypothesis is mainly based on the observation of changes in stone tool technology and human anatomical characteristics over time.

Another site in Morocco that yielded remains of *Homo mauritanicus* with Acheulian tools is Aïn Maârouf, an inland locality discovered in the 1950s (Choubert and Sittler 1957) near El Hajeb, in an open-air context (Hublin 1992). This occurrence has also revealed fossils of large mammals such as elephants and hippos. The presence of *Antelope Parmularius ambiguus*, a species known elsewhere in North Africa only from Ternifine, suggests a chronological affinity between these two sites (Geraads and Amani 1997).

Elsewhere in North Africa, one of the most important Acheulian occurrences in a precise stratigraphical context is the Middle Pleistocene site of Ternifine (Tighennif; Palikao), located in Algeria, near the city of Mascara (Arambourg 1955; Arambourg and Hoffstetter 1963; Balout et al. 1967; Geraads et al. 1986). At this open-air site, large vertebrate fossils (elephant, rhino, hippo) were first unearthed from a dune embankment in the last quarter of the nineteenth century after quarrying was carried out for construction purposes (Pomel 1878, 1893–1897). Following initial excavations, the prehistoric stone industries found there were described by Tommasini (1886). The archaeological site, surmounted by a Muslim cemetery, was systematically exploited some years later when Arambourg recognized its archaeological potential after exploring the area in 1931. Arambourg undertook excavations in the waterlogged basal sector of the mound and exhumed hominin remains (a parietal, three mandibles, and isolated teeth; Hublin 1985) that were attributed to *Atlanthropus mauritanicus* (within the range of Asian *Homo erectus*). These remains were found in association with stone tools ascribed to an *Early Acheulian* morpho-complex, as well as large vertebrate fossils (Arambourg 1955). The site was further excavated from 1981 to 1983 (Geraads et al. 1986).

The Ternifine site deposits, nearly 7 m thick, are composed of alternating layers of clays and sands accumulated from a nearby paleo-lake and the artesian springs that fed into it. Analysis of the surface of sand grains composing much of the infill revealed their origin from eolian transport. The age of the archaeological levels has been assessed mainly from biochronological criteria and paleomagnetic evaluations to c. 0.7 Mya (Geraads et al. 1986; Raynal et al. 2001). The animal fossils collected from the different archaeological levels suggest an open, savannah-like environment surrounding the site. Taxonomically, Ternifine differs significantly from the older sites of Aïn Hanech or Aïn Boucherit, resembling more closely Thomas Quarry 1 at Casablanca (Geraads et al. 1986).

The stone industry includes cobble tools as well as a number of characteristic large flakes shaped into handaxes, trihedrals, and cleavers (Balout et al. 1967; Sharon 2011). These "heavy duty" tools were made from cobbles or slabs of sandstone, quartzite, and some limestone. In addition, there are some small flint flakes (Balout et al. 1967; Geraads et al. 1986). The "cobble opening flake method" (*éclat entame*) was used by hominins to obtain large flakes that needed only modest transformation to be shaped into handaxes and cleavers (Sharon 2009, 2011). Flat cobbles were used to extract *entame* and Kombewa flakes, a distinctive feature of the Ternifine industry that is also observed at some sites in the Iberian Peninsula (Sharon 2011). This particular shared technological know-how could have been transmitted via the Straits of Gibraltar some time after its development (Sharon 2011).

In Tunisia, the excavated Acheulian site of Sidi Zin (El Kef, Belhouchet 2001) was discovered during geological research around Fef (Dumon 1942). Excavations revealed three distinct

archaeological levels containing stone tool assemblages with limestone handaxes and cleavers attributed to the Final Acheulian. Relatively numerous shaped tools (LCTs) are found with some worked cobbles and small cores and flakes knapped from local flint. The stratigraphical sequence is surmounted by a layer of tufa containing a "Mousterian" industry knapped in flint.

Other Lower Stone Age Occurrences

In Morocco, a number of open-air stations were reported to contain scatters of Oldowan-type industries: Tardighet-er-Rahla, Douar Doum (Rabat), and Salé plateau (Biberson et al. 1958–1959; Biberson 1961), but these were later discounted because of their uncertain stratigraphical position and/or doubts concerning their anthropic origin (Debénath 2000). In northeastern Morocco, abundant and remarkably rich prehistoric sites assigned to all periods of human cultural evolution attest to the continuous occupation of the area. But systematic research still needs to be developed to properly document the archaeological treasures of this region. The oldest occurrences are found in deeply eroded, staged alluvial terraces, and conglomerates. Acheulian industries are sometimes found in scatters over surfaces thousands of square meters in diameter, but most occurrences are devoid of faunal remains, and the dating of the sandy, artifact-rich sediment continues to pose methodological difficulties. Some of the sites contain lithics with rolled surfaces attesting to their transport after the erosion and dismantling of their original alluvial context.

In Algeria, there are numerous Acheulian findings in many regions. In the Algerian Sahara, the site of Erg Tihodaine (Djanet, Tamanrasset) has been reported to present a collection of Acheulian implements. At N'Gaous (N'Gaous, Batna), a travertine sequence contains different stratified Acheulian levels in open-air conditions (Sahed 2011). Other sites (Tabelbala-Tachenghit, Djebel Meksem, Tessala, Aoulef, Reggane, Saoura, Bordj Tan Kena) are attributed to the Early Pleistocene on the basis of the composition and general morphology of the stone industries they contain. Unfortunately, most are non-stratified scatters of industries, and they are generally lacking in associated fauna (Champault 1951; Balout 1955; Hugot 1955; Laplace-Jauretche 1956; Alimen and Chavaillon 1960; Ramendo 1963; Roubet 1967; Thomas 1973; Alimen 1978; Heddouche 1980).

One significant open-air site is Errayah, situated in northwestern Algeria (Sidi Ali, Mostaganem). This site has provided a stratigraphical sequence comprising distinct archaeological levels with lithics (large and regular flakes, cores, retouched tools, worked cobbles, handaxes, cleavers, and trihedrals) believed to represent a sequence of successive cultural phases of the Acheulian (Derradji et al. 2017). Raw materials are from local sources and include sandstone, quartzite, and flint. This site is one of many discovered in 1996 during surveying near the coastline at Mostaganem. Excavated since 2001, the site's deposits are mostly sands, accumulated in a fluvial environment upon a clayey Miocene substrate. Unfortunately, there is no fauna at Errayah, and no dates have yet been made available for this site (Derradji 2006; Derradji et al. 2017).

A very rich Acheulian industry is described from another Algerian open-air site – El Mansourah (Constantine) – discovered in 1953. The assemblage is composed of some quartzite handaxes and cleavers, worked cobbles, spheroids, cores, and flakes. Initially, the presence of trihedral forms alongside polyhedrons was interpreted to represent some kind of "intermediate" cultural manifestation between the spheroid-rich industries of Aïn Hanech and the more developed bifacial industries with which they continue to coexist (such as those from Ternifine; Laplace-Jauretche 1956).

In Tunisia, Oldowan industries are poorly documented from precise stratigraphic situations. However, some Acheulian localities have been mentioned following explorations in the early nineteenth century (E. Gobert). Still, the Lower Stone Age remains sparsely documented throughout the country: a few localities are known from Quaternary alluvials in the southwestern Tunisian high plateaus. Flakes, cobble tools, and handaxes were found at two stations near Gafsa, El Mekta, and Redeyef. The latter has yielded some facetted

polyhedrons in flint (Gobert 1910). Some bifacial choppers have also been reported from the northeastern coast of Tunisia (Gragueb and Oueslati 1990). At Wadi Sarrat (Le Kef Prov., Tunisia), there are Acheulian and Aterian lithics in association with rich faunal assemblages (Martinez-Navarro et al. 2014).

Studies of Pleistocene archaeology documenting the presence of Acheulian peoples in southern Egypt were methodically undertaken in the 1930s at Kharga Oasis (Caton-Thompson 1932) and also at Gilf Kebir (Bagnold et al. 1939). Acheulian industries are known from various localities to the south, essentially near the Sudanese border at Bir Tarfawi-Bir Sahara (Schilde and Wendorf 1975, 1981; Wendorf et al. 1976; Hill 2001). The Bir Tarfawi-Bir Sahara region is localized in the Darb el Arba'in Desert (Haynes et al. 1997; Hill 2001), one of the most arid regions of the world today whose history is marked by dramatic climatic change. During the wetter, pluvial periods of the Middle Pleistocene, the region was home to a wide variety of mammals, including hominins, living in a lush, forested environment. A few, isolated discoveries of Acheulian industries have been reported from the Saharan portions of Sudan, Chad, and Libya (Hill 2001). The presence of fossil springs at these localities underlines the need for a source of fresh water for the survival of early humans (Figs. 7 and 8).

In the westerly sectors of Saharan Africa, in Mauritania, pre-Acheulian and Acheulian industries were recognized as early as the 1930s, for example, in the outer ring of the Guelb er Richat structure, also known as the "eye of the Sahara" (Adrar region). The unique elliptical structure of the Guelb results from the differential erosion of rocks composing the dome. After explorations in the region, Théodore Monod discovered and described Early Paleolithic industries from El Beyyed, Oued Akerdeil, Tazazmout, and Aderg (Monod 1975). These finds were to spur further research in the surrounding Quaternary sedimentary sequence by a French-Mauritanian team (Giresse et al. 2012).

Surveying in the Oued Akerdeil from 1998 led to the discovery of more Lower Stone Age sites at El Beyyed, notably Yeslem I, II, and III (De Lumley et al. 2006), which have yielded handaxes and cleavers of extraordinarily large

dimensions. These artifacts form a part of an assemblage that includes chopping tools, cores (mainly discoidal), and flakes, knapped predominantly from locally available quartzitic sandstone. Some faunal remains were recovered from Yeslem III, and the presence of hippopotamus and crocodile remains indicates a watery environment. Overall, the faunal list portrays a savannah landscape with some canopy forest in proximity to water sources, suggesting perhaps a lake-edge environment. This paleoecological assessment is buttressed by data obtained from the sedimentological analysis suggesting a fluvial origin for the deposits. It has not been possible to evaluate the age of the sites using biochronological criteria since the species represented survive in the region up to the end of the Pleistocene.

Waterways, Water Systems, and Hominin Dispersions out of Africa

Close examination of trends in environmental conditions in which Lower Stone Age Pleistocene hominin sites occur in North and Saharan Africa (and elsewhere) evidences the key role played by waterways and water systems for human survival and diffusion. The extension and layout of these waterways dictated emplacements of early human settlements and migration routes.

Observation of the archaeological record from Eurasia during the Early and Middle Pleistocene is essential to understanding why, how, and when hominins from North and Saharan Africa dispersed northward across the Mediterranean seaway. Of paramount importance to this understanding is the Dmanisi site, situated in the piedmont of Georgia's Caucasus Mountain range, since it has provided the earliest evidence of a hominin presence outside of Africa. Juxtaposing Central Asia, Eastern Europe, and the Near East, Dmanisi has yielded Oldowan industries with faunal and hominin remains attributed to *Homo georgicus* and dated to 1.8 Mya (Gabunia et al. 2002). According to current data, the first peopling of Eurasia likely took place when hominins moved out of their African homeland via one or more of four potential passageways: the Gibraltar Straits, the Tunisia-Sicily route, across the Sinai and into the Levant, or via the Bab-el-Mandeb Straits (Fig. 9).

Geographically, migrations across the Straits of Gibraltar into the Iberian Peninsula appear as an obvious route out of the Maghreb – but there are numerous difficulties in providing evidence that early humans were in fact capable of making such a voyage (swimming, navigation). Nevertheless, cultural similarities in lithic assemblages between these two regions have often been noted for the Lower Paleolithic (Sharon 2011) and also for the Middle and Upper Paleolithic (Otte 2007). Today this corridor is only 15 km wide, and this

North and Saharan Africa: Geography and Culture During the Lower Stone Age, Fig. 9 Map showing some Oldowan and Acheulian sites in North and Saharan Africa and in Mediterranean Europe, as well as possible migration routes (*from left to right*: Morocco, Spain via Gibraltar Straits; Tunisia, Sicily route, Levant passageway; Djibouti, Yemen via the Bab-el-Mandeb Straits). Oldowan sites: (Spain) Atapuerca (Sima del Elefante, Gran Dolina levels TD4, TD5, TD6) and Orce (Barranco León and Fuente Nueva 3) (Georgia), Dmanisi; (Algeria) AÏn Hanech. Acheulian sites: (Spain) Atapuerca (Galería, Gran Dolina); (France) Caune de l'Arago; (Levant) Ubeidiya; (Morocco) Casablanca sequence; (Algeria) Ternifine, Mostaganem; (Mauritania) El Beyyed; (Egypt) Bir Tarfawi

distance may have been lessened by lower water levels during glacial events. The highlands present on either side of the straits are clearly visible in fine weather conditions and must have been a lure for human populations through time. Although the depth of the ocean at this particular point has always been too great to allow for the formation of a land bridge, emerged island-hopping remains within the range of possibilities for humans to have crossed over from Africa into Europe (and vice versa).

In Iberia and some areas of southern France, the Acheulian differs compared to the rest of Europe, with the toolkits showing more morpho-technological affinities to the African industries (Sharon and Barsky 2016; Bourguignon et al. 2016). Industries are characterized by large flakes transformed into handaxes and – especially – cleavers. The relative abundance of cleavers in Spanish assemblages constitutes a particularity suggesting African heritage with possible migrations via Gibraltar. In fact, the frequency of these tools diminishes progressively as one moves eastward and northward out of the Iberian Peninsula. The expansion of the Acheulian in Europe postdates that of Africa, and there are a number of sites spanning MIS 16-MIS12 (Villa et al. 2016) (e.g., the Caune de l'Arago in France and Atapuerca in Spain c. 0.6 and c. 0.5 Mya, Barsky and de Lumley 2010; Rodríguez et al. 2011). In Europe, assemblages attributed to the Acheulian are now thought to have appeared as early as 1 Myrs ago (Barranc de la Boella, Vallverdú et al. 2014; Mosequera et al. 2015). Acheulian industries are abundant in the alluvial terraces of Iberia, in particular around the Meseta.

Among the excavated sites, Pinedo (Toledo), situated in river deposits of the middle terrace of the Tage, has yielded cobble tools and trihedrals, as well as handaxes with a low level of symmetry. The assemblage has been described as belonging to an early phase of the Acheulian. Similar industries have been found on the middle terraces of the Tormes, in the northern part of the sub-Meseta (levels III and II, La Maya). The open-air, elephant kill sites of Torralba and Ambrona (Central

Meseta), systematically excavated over large surface areas, are attributed to OIS 12 although precise dates are not available. The assemblages have been assigned to either the *Lower Middle Acheulian* (Howell and Freeman) or to an *Evolved Middle Acheulian* (Bordes and Santonja). Just 18 km southeast of Madrid, on a flood plain of the Jarama riverbed, Aridos I and II are also open-air, elephant kill sites that have yielded similar Acheulian tools.

The longest and most complete archeostratigraphical record on the Iberian Peninsula is from the Sierra de Atapuerca sequence (Rodríguez et al. 2011; Ollé et al. 2013). The karstic system exposed long stratigraphical sections after a trench was dug out for the passage of a cargo train (*Trinchera del Ferrocarril*). Atapuerca's Elefante, Galeria, and Dolina sites have yielded stone industries, fauna, and hominin remains providing an almost complete record of human occupation of Europe during the Pleistocene (c. 1.2–0.25 Kya). At the Elefante site, level TE9 has yielded stone tools and hominin remains dated to 1.2 Mya. The unique handaxe from the Sima de los Huesos, found in association with numerous *Homo heidelbergensis* skeletal remains (28 almost complete individuals), is dated to 0.53 Mya (Bischoff et al. 2007). This tool currently represents the oldest evidence for possible symbolic behaviour in Acheulian culture in Spain in a well-stratified and precisely dated context (Carbonell and Mosquera 2006).

Some authors postulate the Levantine corridor as the most probable route taken by hominins out of Africa and into Eurasia at the beginning of the Early Pleistocene (Agustí and Lordkipanidze 2010), and it is probable that pioneering hominin groups originated from the lands now occupied by the Sahara desert. Human groups producing Oldowan-type industries could have spread throughout North Africa and then into the Western Mediterranean basin, frequenting deltaic and other water-rich environments in search of prey. Coastal routes would have provided resource-rich environments attracting plentiful animals and encouraging hominin settlement. Some well-known archaeological occurrences in Spain bear witness to this early occupation of Europe, at least as early as 1.4–1.2 Mya, at Barranco León and Fuente Nueva 3 (Orce, Andalusia, Toro Moyano et al. 2010b), Sierra de Atapuerca's Sima del Elefante level TE9 (Burgos, Carbonell et al. 2008), and also Gran Dolina TD4, 5, 6 (0.8 Mya, Carbonell et al. 1995). Following the transition to the Acheulian and the appearance of *Homo erectus*/*Homo ergaster*, new waves of migration back and forth from Africa and Eurasia took place from around 1.6–1.5 Mya (Ubeidiya and Attirampakkam; Bar-Yosef and Goren-Inbar 1993; Pappu et al. 2011) and especially after around 0.9–0.8 Mya (GBY, Yunxian; Goren-Inbar et al. 2000; De Lumley and Tianyuan 2008; Sharon 2011) (Fig. 9).

Concluding Remarks

The Aïn Hanech and El Kherba sites (1.8 Mya, Algeria, Sahnouni 2006; Sahnouni et al. 2010) prove that North Africa was inhabited by hominins producing Oldowan industries during the Early Pleistocene, although the paucity of sites in the Maghreb region has led some authors to point out the possible incidental nature of this occupation. Presently, it appears clear that North and Saharan Africa harbor some of the richest Acheulian sites in the world attesting to the occupation of this zone throughout the Middle Pleistocene. Toward the end of the Upper Pleistocene, from around 0.3 to 0.2 Mya, within the context of a continuing climatic trend toward increased aridity, the more complex Middle Stone Age lithic assemblages, with their profusion of divers, small retouched tools, replaced Acheulian industries. In the context of the gradual replacement of *Homo erectus* by *Homo sapiens*, knapping technology continued to complexify, orienting production toward highly standardized flakes.

Continued surveying, cartography, and systematic research will surely reveal more evidence for the earliest occupation of this vast and little known area of our African homeland. In the future, improved and modernized technologies will contribute to the discovery of new Lower Stone Age sites in the more remote and inhospitable areas of the Sahara desert. We may look forward to the establishment of collaborative programs combining the infrastructure and funding

necessary to effectively excavate the sites and adequately curate the artifacts discovered.

Northern and Central Asia: Culture During the Lower Paleolithic Era

A. P. Derevianko and M. V. Shunkov
Institute of Archaeology and Ethnography, Siberian Branch of the Russian Academy of Sciences, Novosibirsk, Russia

State of Knowledge and Current Debates

Recent discoveries of archeologists, anthropologists, geneticists, and other scientists have finally determined Africa to be the ancestral home of humans. The most ancient human sites of *Homo habilis* with stone tools of the Oldowan type dating from 2.4 to 2.6 Ma BP are located mostly in Eastern Africa in the area of the East African Rift.

Around 2 Ma BP, *Homo erectus* expanded beyond Africa and began dispersing over Eurasia. Available scientific data suggest that the first global wave of early human migration moved in two main directions. One direction was connected with the dispersion of ancient hominids across the Near East and Iran to the southern regions of Europe: the Caucasus and Mediterranean. Another wave moved through western regions of Asia eastward. It is hypothesized that most ancient populations moved in two eastward directions. One migration wave passed through the south of the Himalayas and Tibet through Hindustan into East and Southeast Asia, while the other migration wave passed through the Middle East Asian highlands to the areas of Central Asia, Siberia, and Far East.

North Asia

The Karama Lower Paleolithic site has provided the earliest evidence on the human habitation of the southern regions of Siberia. The Karama is located in the upper reaches of the Anui River in the northwestern Altai (Derevianko and Shunkov 2005). Four culture-bearing layers have been established in the proluvial-alluvial deposits on the gentle slope elevated to 50–60 m above the river level. The two upper layers have been established within the middle portion of the profile of boulders filled with reddish-brown loam and sand containing a considerable amount of gravel and gruss. The red-colored deposits were accumulated in the upper levels of the Anui valley during the early Middle Paleolithic according to the data of paleontological analyses (Derevianko et al. 1992a) and RTL-dating (Derevianko et al. 1992b). Dense grey sandy loam with a minor admixture of coarse-grained gravel and weathered rock fragments underlies the red layer. The lower portion of the profile contains two horizons bearing Lower Paleolithic artifacts. This portion represents an intercalation sandy loam and clayey laminations underlain by two layers of the slitozem soil (Derevianko et al. 2005). Compact buried soils are not typical for the Middle and Upper Pleistocene of North Asia. Thus, the occurrence of compact soil serves as indirect support for the early age of this pedocomplex.

The pollen analysis of the samples from the middle and lower portions of the Karama profile suggests the presence of many exotic and warmth-loving species typical for Europe and Far East in the floral associations (Bolikhovskaya and Shunkov 2005). The taxonomic composition of the group of exotic species together with the diversity of the ecological features allows us to estimate an early Middle Pleistocene age for this floral association. Available data of the paleobotanic studies suggest that the early peopling of the Altai took place under the favorable climatic conditions. The region was vegetated by birch and pine forests with an admixture of dark coniferous trees and broadleaf taxa, like elm, hornbeam, lime tree, oak, Manchurian nut tree, hazel, and mulberry tree.

The Karama archeological materials include pebble tools made on large fragments of the local volcanic rocks, mostly effusive spherulite. The industry is characterized by the irregular and parallel flaking. The primary reduction products include core-like pebbles with plain and roughly prepared striking platforms, and spalls with prepared platforms and subparallel flaking patterns of the dorsal surfaces. Sidescrapers of the longitudinal, diagonal, and transversal varieties, most of which bear natural or trimmed backs, constitute the largest tool category. Another large category includes choppers with the straight, convex, and concave working edge. The tool kit also includes denticulate notched and beak-shaped tools. Also such tools as large pebble tools with a nose-like protrusion, thick points with a wide-angle working element, knives fashioned on citron flakes with an edged back, and carinated pebble tools, which morphology is close to that of the core-like scrapers. In general, the industry can be identified as the pebble tool industry. However, the tools from the upper horizons are more progressive. The tool kit of the two upper horizons comprises cores bearing negative scars of parallel flaking, truncated spalls, trihedral point with thin thrusting tip, and carinated end-scraper fashioned through microlaminar flaking.

Geochronology of the Karama culture-bearing horizons is based on climato-stratigraphic characteristics of the lower and middle portions of the Karama sediments, which characteristics suggest the formation of these sediments during the early Middle Pleistocene four stages of various climatic conditions corresponding to two interglacial and two glacial periods (Bolikhovskaya et al. 2006). Correlations of the paleogeographical data with the data of geomorphology and lithologo-stratigraphy make it possible to infer that the sediments containing the two lower culture-bearing horizons were accumulated during a warm period most likely corresponding to the oxygen isotope stage 19 (790–760 ka). The overlying stratum of grey loam was formed during a cool period correlated to the oxygen isotope stage 18 (760–715 ka). The major part of the red-colored sediments with the two upper culture-bearing horizons was accumulated during the warm period corresponding to the oxygen isotope stage 17 (715–660 ka), while the uppermost part of it was formed during the relatively cold period corresponding to OIS stage 16 (660–620 ka).

Archaic pebble tools from Ulalinka, the site located in the lower Katun River basin in the southeastern suburb of Gorno-Altaisk (Okladnikov 1964a), attest to Lower Paleolithic human occupation of the Altai. The excavation trench established at the edge of the terrace 15 m high revealed three sediment packs of varying features separated by long sedimentation hiatuses (Tseitlin 1979). The lower portion of the profile contained clayey dark-yellow sediments intermixed with boulders, gravel, and gruss. Multicolored clay layer is overlain by the stratum of gavel and loam (pebble and boulder – in other description) containing artifacts made on fragmented quartzite pebbles. This stratum is covered by a layer of grey and brown loam; loess-like loam represents the surface layer.

Upper Paleolithic tools have been recovered from the bottom part of the loess-like loam stratum suggesting the Upper Pleistocene age of the sediments. Paleomagnetic analyses have shown the normal polarity of the upper and middle portions of the profile corresponding to the Brunhes period. The lower portion has revealed the reverse polarity that can be correlated to the Matyama paleomagnetic episode (Pospelova et al. 1980). The TL-date of 1.5 Ma BP has been generated for the dark-yellow sediments within the lower portion of the profile (Ragozin and Shliukov 1984). The loam sediments underlain by the horizon bearing Paleolithic artifacts have been correlated to the Krasnodubovsky suite of the upper Ob basin that corresponds to the early Middle Pleistocene. The dark-yellow clay deposits containing the culture-bearing horizon were correlated to the regional Kochkovsky suite and dated to the Lower Pleistocene (Okladnikov et al. 1985). However, according to the primary sources, samples for paleomagnetic analyses have not been collected from the culture-bearing horizon (Pospelova et al. 1980: 10), while the TL-date was obtained from the dark-yellow clay overlain by the boulder and pebble stratum (Ragozin and Shliukov 1984: 9). That means that the Matyama zone of reverse polarity (older than 0.7 Ma) and the TL-date of 1.5 Ma corresponding to the Lower Pleistocene do not represent the age of the culture-bearing horizon. The loam and debris horizon with artifacts that was located at the contact zone between the lower and middle portions of the profile can be correlated with the Krasnodubovski suite by the noted lithological and stratigraphic features. This attests to the early Middle Pleistocene age of this stratum (Adamenko 1970; Tseitlin 1984).

Abundant assemblage of quartzite items from the loam-debris horizon contains such doubtless artifacts as core-like pebbles with negative scars of irregular and amorphous flakes, thick pebbles trimmed along the narrow side to form choppers and chopping tools, scraper-like tools with natural backs and cutting edges prepared with the stepped trimming on flattened pebbles and pebble tools with ovoid spur-like protrusion (Okladnikov 1972; Abramova 1986).

The archaic look of the Ulalinka pebble industry and the assessed age of the country sediments as the early Middle Pleistocene are generally well correlated with the available paleomagnetic analytical data. The sedimentation hiatus between the lower and middle profile portions has been determined through analysis of the fine structure of the geomagnetic field in the

chronological interval of 300–700 ka (Pospelova et al. 1980). The age of the culture-bearing horizon can be determined within the interval of 400–600 ka.

The Lower Paleolithic site of MK 1 is located in the Kuznetsk Depression in South Siberia. It is the nearest site to the Altai. A few lithic implements have been assembled in the course of profile wall cleaning in the Mokhovo coal quarry (Derevianko et al. 1992c). Flaked stones were located on the weathering crust of the Perm sandstone deposit among clusters of siliceous quartz sandstone and gravelite rocks. The Perm sandstone layer is overlain by thick deposits of subaquatic loam of the Kedrovski suite corresponding to the second half of the Middle Pleistocene (M–R) within the regional stratigraphic scale.

The age of the Mokhovo lithic tools has been estimated on the basis of accompanying Pleistocene faunal remains and the data of the carpological analysis of the overlying sediments. The collection of heavily mineralized animal fossils contains metapodia, rid and molar fragments of a large primordial bison, and tubular bone fragments bearing blow marks and some part of the molar plate of an early mammoth form. It is most likely that these are the remains of the Mammuthus trogontherii, a typical taxon of the Viliuy faunal complex of the early Middle Pleistocene. Also, nondefinable tubular bone fragments bearing signs of artificial fragmenting have been discovered (Foronova 1998). The established composition of seeds and fruit from the lower portion of the Kedrovski suite suggests coexistence of warmth-loving and arctic plants under the cooler and more humid climatic conditions than they are nowadays. This is characteristic of OIS stage 9. On the other hand, remains of certain spore-bearing plants – indicators of the "Siberian" Mindel–Riss – have not been noted in this floral complex, which in fact suggest the age of not older than the terminal stage of that period (Nikolaev and Ponomareva 1998). On the basis of available biostratigraphic data, the minimal age of this site has been established as the upper boundary of OIS stage 9 with open lower chronological boundary (Derevianko and Markin 2007).

The MK 1 Quarry has yielded mostly siliceous quartz sandstone fragments, ovoid or rectangular in shape, bearing scars of parallel, uni- and bidirectional flaking of uncertain origin. However, four pieces show signs of premeditated flaking. These are a flat single-platform core with the prepared striking platform and negative scars of parallel elongated removals on the flaking surface, a massive asymmetrical spall, one of the thick-end-bearing pebble cortex that can served as a back and the opposing end served as a cutting edge prepared with scalar, two-step retouch, and two triangular spalls with convex dihedral striking platforms and negative scars of longitudinal and transverse removals. The artifacts bear weathering signs suggesting a long-term exposition that is well correlated with the stratigraphic position of these artifacts under the condition of the long hiatus in sedimentation.

The site of Torgalyk A is located in South Tuva in Uvs Nuur Lake basin, northernmost lake in the Mongolian Grand Lakes Depression. Archeological materials were exposed on top of a 20 m high alluvial terrace on the bank of the Torgalyk River. The surface artifact collection includes lithic tools of varying degree of surface weathering: from the slightly weathered surface to heavy corrosion cortex. Some artifacts demonstrating the heaviest degree of surface weathering have been classified as the pre-Mousterian and oldest tool category (Astakhov 1998, 2008). According to researchers (Astakhov and Yamskikh 1995), the geomorphological layer bearing the artifacts was formed during the second half of the Middle Pleistocene and weathering cortex on the artifact surfaces was likely formed during the same period (climate cooling R_1 or R_2). In this case, geological aspects so not provide any grounds for the artifact age estimation. However, determination of the oldest artifacts with heavily abraded surfaces not typical for the Tuva Middle Paleolithic complexes seems well-grounded. It can be assumed that the artifact surfaces were heavily abraded during the Middle Pleistocene.

Lithic tools made of the local alluvial pebbles, mostly hornfels on aleurolite and fine-grained sandstone, were equally dispersed over the area of about 30,000 m^2. The collection of heavily

abraded artifacts comprises more than 400 specimens including core-like pieces, thick spalls, and archaic tools.

Primary reduction is mostly illustrated by complete and fragmented pebbles bearing signs of core preparation. The subcategory of morphologically clear artifacts is dominated by the flat, mostly elongated, single and double platform cores; the shortened varieties are few. There are also cores bearing signs of the Levallois flaking, bifacially worked cores, and global-shaped varieties with multiple striking platforms. Flaking was executed from the plain striking platforms at the blunt angle. The spalls are large, elongated with heavy percussion bulbs. There are no small spalls wasted in the course of core formation and tool manufacturing in the collection.

Tools were mostly manufactured through hewing and large-faceted retouching. A few artifacts show traces of medium-sized, alternative retouch. Flat hewing, mostly on both faces, is a specific technique of fashioning bifacial tools. Many tools show various notches formed through Clactonian encoches or large-faceted retouch.

The tool kit includes amorphous sidescrapers with the convex and straight uneven cutting edges, massive spur-like points with the triangular cross section, end scrapers on elongated flakes, backed knives fashioned through abrupt retouch as well as notched, denticulate, and beak-shaped tools. The industry includes such specific tools as primitive limands and proto-limands and almond-shaped and ovoid bifaces. The bifacial tools are fashioned on large and thick spalls and elongated, flat, fractured pebbles. One of the surfaces is usually hewed more heavily with the help of large and flat removals; the other surface is flattened through broad and shallow flaking. Uneven edges on some artifacts were smoothed out through large-faceted retouch. The bases are mostly sharpened, straight, and beveled. The industry belongs to the Early Paleolithic pebble tradition based on certain elements of the Levallois flaking and the primitive technique of bifacial hewing.

A few artifacts of similar typology and degree of surface abrasion have been recorded from the two other sites at the Torgalyk, namely, at Torgalyk B and Torgalyk 1 that was defined as a "workshop on the river bank" (Derevianko et al. 1999).

In the southern part of Middle Siberia, Upper Paleolithic artifacts have been recorded within the surface-collected tools from the Kurtak archeological area in the north of the Minusa Depression. Clusters of archaic implements bearing aeolian abrasion signs have been collected from the beach of the Krasnoyarsk Dam in the areas where the Pleistocene deposits were washed out. These Pleistocene deposits have been located in the stratigraphic context between the buried soil of the OIS substage 5e and the bed of the Pliocene terrace of the Yenisei (Drozdov et al. 2000). The animal fossils associated with the same stratigraphic unit contain bones of the Khazar mammoth, large caballoid horse of the Khazar type belonging to the Early Mammoth complex (*Khronostratigraphia*... 1990). All these animal types represent typical representatives of the animal community of the second half of the Middle Pleistocene.

Basing on the technical–morphological features, researchers regard the archeological materials from the site of Razlog 2 as the oldest artifacts in the Middle Siberia (Drozdov et al. 2001). A small collection of artifacts (about 60 specimens) was assembled from the Yenisei bank. The industry belongs to the pebble type based on radial and subparallel reduction strategies. Disc-shaped and subrectangular cores, chopper-like tools with the transverse edge bearing signs of hewing, and tools with nose-shaped protruding parts are made of thick quartzite pebbles from the river alluvium. The Razliv site has yielded a mostly similar collection of archaic pebble implements. In addition to the abovementioned tool types, the Razliv tool kit includes few radial cores with two flaking surfaces, orthogonal cube-shaped cores, bifacially worked chopping-like tools, and backed scraper-like tools fashioned on citron flakes. Two loci have been established in Berezhekovo. The site has yielded pebbles with signs of hewing and retouched spalls that were recovered in association with the motley debris sediments of the second half of the Middle Pleistocene and attributed likely to the industry type described above.

The Kamenny Log site has produced the lithic artifacts with the heavily abraded surfaces that look like more developed Early Paleolithic industries. The artifact collection includes cores bearing traces of the Levallois and proto-prismatic reduction, triangular spalls with the prepared striking platform with the convex center in addition to the large pebble tools and backed citrons. The excavation area revealed a radial core and few spalls that were detached from this core and illustrated the core utilization process. This finding provides the evidence that the archaeological materials were not heavily washed out.

Abundant and interesting Lower Paleolithic materials have been reported from the south Angara basin (Medvedev 1975). Dozens of archaic quartzite implements bearing heavily weathered surfaces have been collected from surface clusters and individually along the right-side (eastern) sloppy bank of the Angara. The artifacts were mostly discovered on high hills like Mts. Olonskaya, Balushkina, Ponomarevskaya, Igetei, Tarakhai, and others. The hills represent the remnants of the ancient denudation surface elevated to the level of the watershed plateau. The artifacts were exposed on tops of the hills among the outcrops of the Jura cobbles and pebbles or else were shifted down by the erosion processes over the southern and western hill slopes at the height of 80–150 m above the valley bottom. Artifacts of the similar type and degree of surface abrasion were also discovered at the lowermost part of the sand and debris layers that were formed during the OIS 4 at the level of medial Angara terraces and shifted down on the contemporary banks of the Bratsk water reservoir.

Judging by the geomorphological position of surface exposing and conditions of relative stratification of the artifacts with abraded surfaces, the artifacts can be attributed to the period not younger than the first glacial period of the Upper Pleistocene (Tseitlin 1975). However, redeposition of the heavily abraded artifacts as well as the absence of any biostratigraphic and geochronological data do not make it possible to estimate the age of these findings more precisely. In this situation, the noted degree of weathering of the worked surfaces can be regarded as an important age indicator. The established techniques of age estimation make it possible to regard the artifacts with the heaviest degree of surface weathering as the oldest archeological materials in the region and assess their age as not younger than the second half of the Middle Pleistocene (Medvedev 2001).

The total collection of the heavily weathered artifacts comprises about 1000 fractured quartzite items including numerous cores, pebble spalls, and comparatively few typologically distinct tools. Various forms of cores demonstrate various reduction strategies simple flaking of quartzite pebbles without special preparation of the striking platform and flaking surface and specialized technique of fashioning pyramidal, convex flaking surfaces with the aid of continuous, radial hewing of both faces. The typical varieties of cores are the single-platform triangular cores with one flaking surface bearing sign of convergent flaking and flat rectangular cores with parallel flaking scars over one or two prepared striking platforms. Elongated laminar spalls including those with the parallel flaking pattern on the dorsal face, straight or curved symmetrical profile and striking platform with large facets represent the developed reduction technique.

The tool kit is dominated by the longitudinal, transverse, and combined varieties with uneven cutting edge manufactures mostly with the large retouch facets. Few pointed tools on thick convergent spalls represent likely dejete. Choppers with the straight, convex, and triangular edge have been fashioned on quartzite pebbles. There is a specific tool representing a pointed cleaver on an elongated, large, and flat spall with the transverse cutting edge and hewing signs on one surface of the lateral sides.

The artifacts collections from the Angara basin can be classified into the Tarakhai and Olon trends (Medvedev 1983). The industries of the Tarakhai trend represent pebble traditions. The technique of citron flaking was often used; various choppers represent the most typical implement in the tool kit. The Olon trend is closer to Acheulian tradition. Ovoid core-like implements bearing signs of bifacial, radial working are most typical, while the proportion of pebble tools is comparatively small.

Quartzite implements close to the tool described above in the shape, and weathering

signs have been recorded in the northern part of the Bratsk dam (Volokitin 1992). In the Angara–Okinsky basin in the erosion area of contemporary river banks that are situated at the elevation of 70–80 m above the original river level (the sites of Monastyrskaya Gora, Mys Dunaisky, Zharik), about 200 artifacts with heavily weathered surfaces were collected. Within the collection of the most archaic quartzite artifacts, ovoid cores with radial flaking patterns on the flaking surfaces, rectangular single-platform cores of the parallel reduction, longitudinal, transverse, and dejete sidescrapers with natural backs made on thick cortex spalls or on knapped pebbles, pebble choppers with convex abrupt edges and large flakes bearing discontinuous retouch traces have been noted.

The Balyshevo site located in the eastern outskirts of the Angara–Lena watershed plateau has produced interesting data relevant to the assessment of the geological age of the archaic and weathered technocomplexes from the southern parts of Middle Siberia (Zadonin 1992). The first heavily weathered quartzite artifacts were assembled from the tilled left-side slope of the Lena elevated to about 40 m above the water level. The test excavations at one of the area of the artifacts scattering yielded heavily weathered artifacts from the depth of 0.4 m in association with the weathered pebble and gravel layer on the top of the solifluction deposits aging from OIS stage 4. The complete petrographic identity of the pebble context and the associated archaic Paleolithic artifacts as well as a convergent sidescraper and a flake detached from this implement discovered in the excavation area attest to the fact that the artifacts were accumulated in association with the quartzite outcrops rather than were slid down the slope of redeposited in any other way. The predominance of primary reduction products in the collection of artifacts provides an indirect support to this inference.

In total, 130 quartzite implements have been collected from the surface and within the excavation area. The manufacturing features and the degree of worked surface weathering make it possible to establish a single technocomplex. The collection includes ovoid cores of radial pattern of flaking from one pyramidal-shaped or two convex surfaces and the cores with the convergent flaking pattern. Also, choppers on thick pebbles and sidescrapers on large cortex and semi-cortex spalls with convex, stepped edge, laminar spalls bearing marginal retouch and shortened flakes including those detached from the prepared striking platforms.

The Balyshevo industry is likely one of the youngest lithic industry among the oldest Paleolithic materials in Middle Siberia. However, heavily weathered surface that was formed under the glacial conditions during the Upper Pleistocene (OIS stage 4) did not support the hypothesis of the Middle Pleistocene age of these heavily weathered artifacts that was proposed by G.I. Medvedev (2001).

The data on the Early Paleolithic from the eastern shore of Lake Baikal (Trans-Baikal) are contradictory. Zasukhino probably represents the earliest archeological site in Trans-Baikal. Zasukhino was established within the biostratigraphic profile in the quaternary deposits of western Trans-Baikal. According to the published data (*Prirodnaia sreda*… 2003; Lbova 2005), knapped rocks were noted in four loci within this biostratigraphic profile. The artifacts were noted in association with the laminations of buried soil within the Middle Pleistocene deposits containing faunal remains of the Viatka theriocomplex. The artifacts were recovered from the contact zones of four lithological units. The lowermost unit has shown the reverse polarity and attributed to Matyama episode. The overlying sediments were formed under the normal polarity of the Earth's magnetic field. The RTL data suggest the chronological interval of 190–900 ka. Despite certain discrepancies in the straigraphic location of lithic artifacts in diagrams and descriptions, the geological age is not younger than the Middle Pleistocene.

A cluster of large pebbles noted in one of the lowermost layers containing cultural remains is noteworthy. Lenses of charcoal and fragmented burnt bones make it possible to interpret the pebble cluster as a hearth pavement. If it is really an intended artificial construction, the hearth is the oldest evidence of premeditated usage of fire in

Northern Asia. However, available publications do not provide comprehensive information concerning the features of the construction, its planigraphic context, sediment microstratigraphy, and others.

The petrographic composition of the knapped pebbles includes quartzite, vein quartz, granite–gneiss, and granite. These rocks, with the exclusion of granite, are characterized by the poor isotropic features and are not good for knapping, which features of the used raw materials make cultural attribution of the artifacts difficult. Within the rock pieces, knapped pebbles and fragments with pebble cortex. Some pieces resemble sidescrapers and choppers. Some pebble might serve as hammerstones and anvils. However, the published drawings and photos of these pieces (*Prirodnaya sreda.*. 2003) arouse doubts in the artificial origin. Such controversy in the attribution of rock pieces to artifacts requires group decisions. If the Zasukhino findings are defined as artifacts, it will give researchers the grounds to speak about human habitation of Trans-Baikal prior to the Upper Pleistocene. Presently, this possibility is only an assumption that was made by A.P. Okladnikov more than half a century ago (Okladnikov 1959).

Diring Yuriakh is the earliest Paleolithic site in Yakutia. The site is located in the middle Lena basin to the north from latitude 60. According to the recently published data (Mochanov and Fedoseeva 2002), the excavation area at Diring Yuriakh exceeds 36,000 m^2 and yields 51 clusters of cultural remains totaling to 5000 items.

Artifacts were recovered from the sediment of the 105–120 to 125–135 m high terraces overlying the common basis of the Cambrian sandstone located at the relative height of 105 m. According to Y.A. Mochanov, the culture-bearing horizon represents a thin (3–5 cm) layer of weathered pebbles and gravel. It overlies the red Pliocene sand deposits with frost clefts. Above it, there is a layer of grey loam of the horizontal laminar structure. Mochanov argues that the sediments underneath the culture-bearing horizon belong to the riverbed fascia, while those above it belong to the floodplain and old bed fascias of the alluvium of the Tabaga accumulative cycle of the Lena basin. The age of that cycle has been estimated within the range of 3.2–1.8 Ma (Mochanov 1988a). Along with the geological assessment of the age, other scientific studies have been carried out at the site. However, the results of these studies in the interpretation of the main researcher (Mochanov 1992) and the scientist who made the analyses (Penkov 1992) are ambiguous and allow for various age estimations.

With regard to the geological age of the containing sediments, Y.A. Mochanov considers the Diring Yuriakh materials as belonging to the earliest stages of the Paleolithic and believes that the only reasonable way is to compare them exclusively with the Oldowan culture in Africa (Mochanov 1988b). The Diring Yuriakh lithic industry is really archaic. The industry is characterized by irregularly split quartzite pebbles and cobles that were fashioned into various choppers, sidescraper-like implements and nosed tools as well as amorphous pebble spalls with unclear signs of premeditated knapping, anvils, and hammerstones. All the quartzite pieces show heavily weathered surfaces.

The geological and archeological old age of Diring Yuriakh that is not usual for high latitudes makes Y.A. Mochanov revive the idea of non-tropical origins of humans (Mochanov 1992). Not going into details of this issue (Ranov 2005), it is necessary to stress the key point in the Diring Yuriakh Paleolithic is the geological estimation of the age of the culture-bearing horizon being the main point of controversy between Y.A. Mochanov and his numerous opponents. V.A. Ranov and S.M. Tseitlin (Ranov and Tseitlin 1991) visited the site, studied the lithological and stratigraphic situation, and proposed a well-grounded critical assessment of the sediment origins and its relative age. According to the observations of these competent experts, the culture-bearing horizon is associated with the lower portion of the grey sediments at 5–25 cm above the top of the red Pliocene sand layer in the profiles of the 125–135 m high terrace. Thus, the culture-bearing horizon does not directly contact the Pliocene deposits as in Mochanov's interpretation. Hence, on top of the 105–120 m high terrace, the pebble and gravel sediments containing cultural

remains occurred on the layer of red pebbles because of the denudation processes. Ranov and Tseitlin argued that the Diring Yuriakh terrace was formed in two stages separated by a long hiatus. Deposition of the red, riverbed pebble and sand took place during the Pliocene, while the subaquatic grey sand and sandy loam containing cultural remains were deposited during the Pleistocene. The grey sediments were likely accumulated under the conditions of slow flowing water from a pond dammed by melting ice, most likely during the OIS stage 8. The hypothesis on the formation of the grey deposits during the Pleistocene is shared by other researchers (Alekseev et al. 1990; Waters 1999). The American researchers based their inferences on their TL dates of 267 ± 24 ka BP for the sand deposits overlying the culture-bearing horizon and 366 ± 32 ka BP for the underlying frost vein (Waters et al. 1997). Despite certain criticism of the reliability of these TRL-dates (Huntley and Richards 1997), they are well correlated to the main point of Mochanov's opponents on the Middle Pleistocene age of the sediments containing cultural remains.

The idea to assess the Diring Yuriakh age on the basis of comparisons of the technical–typological features with the earliest African complexes (Mochanov 1992) does not seem well-grounded either. Given the general similarity within a single stage of phased development, the more precise technical–typological comparisons show mostly different rather than similar features. For instance, the Diring Yuriakh collection does not include any cores, polyhedrons, disc-shaped cores, and small flake tools typical for the Oldowan (Leakey 1971). These distinctions point out the formality of comparisons of the industries from such distant regions as the northeastern part of Africa and the northeastern part of Asia. Thus, neither primitive knapping techniques nor archaic look of the pebble implements does not provide any reasonable grounds to regard the age of the Early Paleolithic site of Diring Yuriakh as older than the second half of the Middle Pleistocene.

Two other loci where archaic quartzite implements were found have been recorded in the middle reaches of the Lena (Alekseev and Cherosov 1992). Artifacts have been recovered from the layer of weathered pebble and gravel underlying the layer of modern soil on top of a 125–130 m high terrace-like surface in the Olekma River mouth. The Yunkiur site located in the vicinity to the city of Olekminsk, weather artifacts have been discovered among the layer of ventifacts that was exposed in the wind-blown sediments at the depth of 9 m from the surface of the 35–40 m high Lena terrace during the quarry works. Judging by the published drawn images and the morphological descriptions of the findings (Alekseev and Cherosov 1992: 137, 139, 141, 142), attribution of the Yunkiur items as artifacts arouses considerable doubt. In contrast, the Ust-Olekma collection includes distinct choppers with well-prepared edges, polyhedrons–spheroids, trihedral chopping tools and flakes, hammerstones, and anvil. The minimal geological age of the weathered pebble layer that was redeposited in subaerial, slope sediments in the upper portions of terraces most likely corresponds to the Upper Pleistocene, yet its initial geochronological position is not clear.

The sites with coarsely flaked pebbles that were discovered in the Amur River basin in the 1960s are noteworthy, especially from the historiographic point of view. This discovery aroused discussion about the possible peopling of North Asia in the Early Paleolithic (Okladnikov 1964b). Initially, such fractured pebbles have been discovered at Filimoshki in the upper reaches of the Zeya. The artifacts were uncovered from the upper portion of the riverbed alluvial fascia on the 10–12 m high left-bank terrace. The alluvial fascia overlies the bed of sandstone intercalated by laminations of carbonaceous shale. The culture-bearing horizon was overlain by laminations of sand and sandy loam. The layer of riverbed pebbles contains fractured pebbles of fine-grained quartzite. The variety of artifacts includes amorphous cores without prepared striking platforms, primitive sidescrapers and choppers with minor preparation of the edges, and specific tools

with nose-shaped protrusions. Similar fractured pebbles have been discovered in analogous context in several other loci at the mouth of the Ust-Tu spring at the right-side bank of the Zeya and in the vicinity to the village of Kumary in the upper Amur (Derevianko 1983).

In general, the considerably archaic look of the flaked pebbles and their relative stratigraphic position under the condition of possible repeated redeposition attest only to the minimal age of the findings in the range of the geological period when the containing sediments were formed. Initially, it was presumed that fractured pebbles were redeposited in the upper portion of the riverbed pebbles of the so-called Belogorski suite during the second half of the Middle Pleistocene (Ibid., p. 49). However, additional studies of the lithological structure of the 10–12 m high terrace 2 of the Zeya along with the data of the pollen analysis and mechanical composition of the sandy fill of the pebble layer make it possible to estimate the geological age of this layer as not earlier than the second half of the Upper Pleistocene (Tseitlin 1979). Thus, the presumed old age of these findings have not been supported by geological data, and the artifacts can be regarded only in the general context of the earliest archaeological sites in North Asia.

The similar inferences concern another unusual Paleolithic finding from the village of Bogorodskoe in the lower Amur basin (Okladnikov 1979). On the tow path on the Amur right-side bank at the foot of 20 m high terrace, a bifacially worked cordiform tool with the symmetrically convex cross section made of a dark volcanic rock was discovered. On the basis of the noted shape and the technique of working, A.P. Okladnikov interpreted this tool as an Acheulian hand axe. He argued that this hand axe fell down from the Middle Pleistocene deposits of the high floodplain terrace of the Amur and attributed it to the earliest Paleolithic stage. In fact, this tool represents a thick pebble tool with the natural back and shows bifacial working through removing short and broad spalls. The stratigraphic position of this tool is unclear; hence, its age has not been defined.

Fractured pebbles from the Sennaya-1 site are regarded as the evidence of the initial human occupation of Sakhalin. The site is located on the southeastern coast of the island (Vasilevsky 2008). The excavation trench at the gently sloping coast revealed the proluvial–alluvial deposits containing fractured pebbles. This layer has been established overlying the bed of the Middle Pleistocene sea terrace elevated to about 50 m above the sea level. The lowermost portion of the profile reveals clay and sand of subaquatic origin. Above it, a layer of dense loam intercalated with lenses of sand and sandstone pebbles and cobbles. The loam layer is overlain by a layer of light-yellow sandy loam with the humus horizon of soil on top.

The OSL dating of the middle portion of the profile suggests the age of this deposit in the range of 154–197 ka. The data of spore-pollen analyses of the lower and medial part of the loam horizon suggest that accumulation of this layer took place under the relatively warm climatic conditions favoring vegetation of dark-coniferous forests with admixture of broadleaf species. On the basis of these data, the following sedimentation sequence has been proposed. The clay and sand deposits represent the sediments of marine lagoon; the layer of loam with sand admixture was accumulated initially as the floodplain fascia during one of the warm periods of the Middle Pleistocene and as the terrace-forming sediments during the subsequent cold stage of the Middle Pleistocene. The layer of yellow sandy loam was formed during the late Upper Pleistocene, while the humus-containing horizon appeared during the Holocene.

However, the proposed geochronological scenario is poorly correlated with the lithological features of the sedimentation sequence. According to the established stratigraphic column and the lithological features (Vasilevsky 2008: 74, 75, 292), the layers attributed by A.A. Vasilevsky to distinct geological periods and paleogeographic stages are intermixed at some portions, and the continuous sequence of sediments does not show any traces of sedimentation hiatuses. The light-yellow sandy loam

overlies the dense loam without any traces of long hiatus, while according to the proposed interpretation, these two layers are separated by the hiatus lasting not less than 100,000 years. The biostratigraphic interpretation of the sediments also seems doubtful. It is based on fragmentary data from two pollen samples containing few pollen seeds, while the palynological conclusion has been made on solitary pollen seeds of oak and elm noted in the samples (Vasilevsky 2008: 250, 251). The noted stratigraphic discontinuity and the lack of reliable paleontological data make the OSL-dates debatable and require better support of the Middle Paleolithic age for the sediments containing cultural remains.

The relative age of the sites can be established on the basis of the stratigraphic position of pebble implements. Fractured pebbles were noted throughout all the lithological layers within the profile. However, about one-half of all the fractured pebbles have been recovered in association with the sediments of the terminal stage of the Upper Pleistocene and Holocene (Vasilevsky 2008: 83). Artifacts from the underlying layers demonstrate the same features as the Pebbles from the upper portions of the profile do. It makes it possible to regard the whole collection as a single technocomplex with the geological age close to the Pleistocene–Holocene threshold.

The artifact collection mostly includes indistinct fractured quartzite, flint, argillite, and other pebbles. A.A. Vasilevsky has defined core-like pebbles, thick flakes, cortical spalls, typologically indistinct sidescrapers, implements with spur-like protrusions, and knives fashioned on cortical segments. A.A. Vasilevsky argued that the tools were fashioned through mostly longitudinal and diagonal knapping with the aid of hard hammer or through a blow against the anvil. Other techniques include detaching narrow diagonal spalls and percussion technique. A.A. Vasilevsky defined these implements as remains of the Lower Paleolithic pebble industry on the basis of the noted simple knapping and secondary working techniques. It seems that the indistinct typological features of this industry can be explained by the fact that the majority of the artifacts represent defected or broken implements that are not suitable for further usage. The artifacts seem to represent raw material testing at the workshop that was destructed by slope processes judging by the deposition features.

Central Asia

According to the latest data based on the oldest Paleolithic finds from the loess–soil deposits of Tadzhikistan (Kuldara, Khonako II, Obi-Mazar-6), the appearance of *Homo erectus* in Central Asia refers to the period between 600 and 900 ka (Ranov and Schaefer 2000; Ranov 2001).

In Acheulian, technocomplexes with bifaces have been discovered in the Mugodjari Mountains in the northwestern part of Kazakhstan and represent the most interesting Early Paleolithic assemblages (Derevianko et al. 2001). The Acheulian sites of Mugodjari 3–6 represent clusters of heavily and moderately weathered artifacts on the surface of deluvial shelves and on hilltops at the outcrops of sandstone that was the main raw material for tool production. Among the collected artifacts, the sets of Acheulian foliate, ovoid, and cordiform bifaces are most noteworthy. Also cores bearing signs of the Levallois flaking, various types of sidescrapers, and notch-denticulate tools have been identified.

Other well-defined Acheulian bifaces have been recorded in the Mangyshlak Peninsula (Medoyev 1982), in Bale Hills, Semizbugu, locus 2 in the northern portions of Balkhash region (Medoyev 1970; Derevianko et al. 1993), in the southwestern and northeastern parts of the Kazakh hill country (the sites of Zhaman-Aibat 4 and Vishnevka 3) (Klapchuk 1976; Voloshin 1988), and in the left-side bank of the Irtysh in the Pavlodar region (Kudaikol) (Medoyev 1968). The lithic collections from these sites include bifacially worked tools of various types as well as products of the Levallois reduction, various sidescrapers, and notch-denticulate tools.

Archeological materials from Koshkurgan 1 located in the southwestern part of the Karatau mountain range represent a special type of the Early Paleolithic industry (Derevianko et al. 2000b). Lithic artifacts have been recovered

from the stratified context in association with animal remains of the Koshkurgan (Tiraspol) faunal complex dating from the second half of the Middle Pleistocene. Cultural remains have been recovered from the subaquatic sediments of the ascending spring within the gryphon travertine formations. The age of the fossils has been estimated through the ESR analysis in the range of 400–500 ka. Archeological materials have been defined as the pebble industry of the microlithic type. Tools were made of small pebbles of various rocks. The size of the artifacts does not exceed 4–5 cm. The Levallois and single-platform cores, shortened non-faceted spalls, simple longitudinal and double sidescrapers, and notch-denticulate tools represent the most typical artifact types.

The site of Shoktas 1 was established in the travertine sediments of the gryphon in the vicinity to Koshkurgan (Derevianko et al. 2000b). The Shoktas artifacts demonstrate technical–typological features similar to those from Koshkurgan and have been defined as the Early Paleolithic industry of small tools.

The sites of Borykazgan, Tanirkazgan, Akkol, and others (Alpysbayev 1979) from the northeastern piedmonts of the Karatau represent another type of the earliest lithic industries in Kazakhstan. These lithic industries are characterized by the pebble nonstandard cores, large chopper and chopping tools, and few flake tools. Some researchers point to the minor "proto-Levallois features" (Liubin 1970) and some clearly Levallois technological features (Medoyev 1982).

The majority of the Early Paleolithic collections in Mongolia belong to the pebble industry type. The most archaic artifacts have been reported from several loci of Nariin Gol 17 in the northern part of the Lake Valley (*Kamenny vek*... 2000e). The heavy to moderate degree of artifact surface aeolian abrasion and the position of the artifacts at the foothills and on the slopes of a high Pliocene terrace suggest the Lower Pleistocene age to this site, which is the earliest in the Mongolian Paleolithic. The Nariin Gol lithic collection includes such noteworthy items as large multi-platform orthogonal cores, cores with one flaking surface bearing the parallel reduction pattern, segments, and specific scraper-like tools.

The lithic collections from the so-called Mankhan cluster of sites in the Mongolian Altai represent the next stage of the Early Paleolithic and belong to the Middle Pleistocene according to the arguments of the researchers (*Kamenny vek*... 1990). The assemblages from these sites comprise comparatively few weathered artifacts including pebble cores bearing irregular flaking patterns, Levallois and parallel reduction cores, choppers, and notch-denticulate tools.

A.P. Okladnikov (1983) was the first to identify bifaces of the Acheulian type within the Paleolithic assemblages from the sites of Dno Gobi (Bottom of Gobi) and at Mt. Yarkh. Almond-shaped, ovoid, and subtriangular bifacial tools along with the disc-shaped, proto-Levallois, and Levallois cores represent the most archaic part of the chronologically heterogeneous assemblage of the surface-collected artifacts (Okladnikov 1986).

Archeological studies in the southern regions of the Gobi Altai provide researchers with the new data supporting the conception of dispersal of the Acheulian features in the Mongolian Paleolithic industries. The bifacially worked tools associated with the Levallois reduction products have been recorded within the collections of the heavily abraded artifacts collected from the sites in the Flint Valley (Derevianko et al. 1996), Trans-Altai Gobi (Derevianko et al. 2000c), lower stratigraphic layers in the Tsagan-Agui cave site (Derevianko et al. 2000a), and the Tsagan-Agui workshop site located at the cave (Derevianko et al. 2000d). Available data of the physical analyses of the age of the Tsagan-Agui sediments suggest that the Levallois–Acheulian traditions emerged in this region as early as in the Middle Pleistocene.

Archeological materials from Uench-1 illustrate development of the Early Paleolithic traditions during the terminal stage of the Acheulian period (Derevianko and Petrin 1992) or else during the initial Mousterian period (Okladnikov and Abramova 1994). The Uench lithic industry is distinct among other technocomplexes in the used raw materials and smaller lithic implements including the Levallois items, various sidescrapers, and backed and notch-denticulate tools. It should be

noted that the Levallois technique of stone working is the major characteristic feature of practically all the early lithic industries in Mongolia.

Northern Asia: Origins and Development of Agriculture

Tracey Lie-Dan Lu
Department of Anthropology, The Chinese University of Hong Kong, Hong Kong, China

Introduction

The origin and development of agriculture is one of the most important processes in human history, as it has fundamentally and irreversibly changed not only the subsistence strategies but also the whole trajectory of cultural development of human beings. Agriculture has led to the occurrence of labor division, professionalization, social inequality, and civilizations and has produced long-lasting impact on the physical evolution of human beings, the environment, and natural resources, including the soil, climate, landscape, and many flora and fauna species in the earth.

Because of these significances, the study of the origin of agriculture has been one of the most important topics in the field of archaeology, anthropology, genetics, history, historic ecology, linguistics, paleozoology, paleobotany, as well as other related disciplines of sciences and social sciences. Based on studies of these disciplines

since the 1910s, it is quite clear now that Northern Asia, which includes eastern Russia, China, Mongolia, Japan, and Korea, and stretches between latitudes approximately 72° and 19°N, and longitudes between approximately 70° and 145°E, has witnessed an independent origin and development of agriculture, with its temperate eco-zone located between latitudes approximately 43° and 25°N being the core area.

Definition

There are various definitions of "agriculture." In this entry, "agriculture" is defined as a subsistence strategy of systematic and continuous cultivation of plants and husbandry of animals, which facilitates the domestication and continuous evolution of certain plants and animals, and the development of human beings and their cultures. "Domestication" is the dynamic process of human manipulation and the genetic and physical evolution of plants and animals, which creates new species that have to rely upon human beings for their survival, and vise versa (Lu 1999, 2006). "Culture" is the integrated and dynamic system of technology, social structure, symbols, beliefs, behavior patterns, and other cognitive aspects learnt and transmitted between members of a given human society in a given period of time (Kottak 2002).

Historical Background

Studying the origin and development of agriculture in Northern Asia is primarily a result of the occurrence of modern archaeology in this area. In 1927, Swedish geologist and archaeologist Johan G. Andersson discovered rice husks on pottery dated to approximately 7,000 years ago in Yangshao, Henan Province, China (Andersson 1934). Rice remains have been found in archaeological sites of the Yayoi culture dated to between approximately 2,800 and 2,400 years ago in Japan from the 1930s onward (Misaka and Wakabayashi 2011). In the decades that followed, particularly after the 1970s, hundreds of archaeological sites dated from approximately 15,000 years to 4,000 years ago have been excavated in Siberia, Mongolian area, the Yellow and the Yangzi River Valleys, South China, Japanese archipelago, and Korean Peninsula; research methods from botany, zoology, soil analysis, isotopic analysis, genetics, chemistry, and starch analysis have been applied to archaeological studies, and enormous amount of plant and animal remains have been found and analyzed. The result provides substantial information for the understanding of the origin and development of agriculture in Northern Asia, although there are remaining questions.

Based on these studies, it seems that there are probably two centers of the origin of agriculture, with cultural contacts, in Northern Asia (Lu 2006). The first center expands from the southern edge of the Inner Mongolia to the middle to lower Yellow River reaches, where the cultivation and domestication of foxtail and broomcorn millet (*Setaria sativa* L. and *Panicum miliaceum* L., respectively) occurred at around 8,100–8,000 years ago; the second center locates mainly in the middle to lower Yangzi River valley and the adjacent Huai River, where the cultivation and domestication of one subspecies of rice (*Oryza sativa japonica*) originated at approximately 9,000–8,500 years ago (Lu 1999; Zhao 2011) (Fig. 1). So, what are the causal factors of nature and culture for the origin of agriculture in this area?

Climate and Environment

Northern Asia is a landmass of great ecological and cultural diversity. Geographical, pollen, phytolith, and soil analyses have been used to investigate the climate, natural resources, and the landscape changes in this area. Geographically, the northern part of Northern Asia is dominated by mountains, including the Altai, Tian shan, Kunlun shan, the Khreber, the Stanovoy, and the Da Hinggan Ling Mountains; between the mountains there are the Siberia, Mongolian, Qinghai-Tibet, and the Yungui Plateaus, and many rivers with the Yellow and the Yangzi River being the longest.

The climate in the continent of Northern Asia is controlled by the northward summer monsoon from the Pacific Sea and the southward winter monsoon from Siberia, while the climate of the Japanese Archipelagos and the Korean Peninsula is also affected by sea currents. Generally speaking, the Last Glacial Maximum had significant impact on this landmass, particularly on areas north of latitudes 22°N, as the climate became much colder and drier during that period (Lutaenko et al. 2007; Lim and Fujiki 2011). The rising and falling of sea levels and geological movements also play important roles in the local climatic changes from the Last Glacial Maximum between approximately 22,000 and 15,000 years ago, to the gradual warming up period between 15,000 and 12,000 years ago, and the warmer and wet Holocene Optimum between about 7,000 and 4,000 years ago (Lutaenko et al. 2007; Lim and Fujiki 2011). The period from 12,000 to 7,000 years ago saw the origin and development of prehistoric agriculture in this region.

Foragers Prior to the Occurrence of Agriculture

Between approximately 15,000 and 10,000 years ago, pottery, composite tools made by microblades and organic materials, and grinding stones independently occurred in Siberia, Japan, the middle Yellow River Valley, and South China, as new implements used by human beings to exploit different resources and develop broader spectrum subsistence strategies in various environments, including the collection of grass seeds, tubers, nuts, shells, and fishing and hunting (Lu 1999, 2006, 2008; Liu et al. 2010; Crawford 2011). The earliest rice phytolith dated between approximately 15,000 and 12,000 years ago are found in the Xianrendong and Diaotonghuan site in the middle Yangzi Valley, the Yuchanyan site at the northern border of South China, and the Zengpiyan cave in South China (Lu 2006, in press; Zhao 2011). Rice husks and phytolith of leaves have been found at Shangshan, the lower Yangzi Valley and are dated to between 10,000 and 7,500 years ago (Zhao 2011). However, it is not clear whether rice phytolith or remains found in the aforementioned sites are wild or domesticated species, nor is it certain that rice was cultivated or just collected for food and/or fuel, or for other purposes (Fig. 1) (Lu 2008; Zhao 2011). Nonetheless, these discoveries illustrate that rice was exploited by human beings in the temperate zone in Northern Asia by 12,000 years ago.

The early exploitation of millets, on the other hand, is unclear. Use-wear analysis on stone flakes found in Xiachuan (Fig. 1), Shanxi Province, China, indicates that cutting grasses was practiced at around 12,000 years ago in the middle Yellow River Valley (Lu 1999), but as millets cannot produce identifiable phytolith (Zhao 2011), and flotation has not been carried out in late Paleolithic sites in this region, the exploitation of wild millets remains to be investigated.

The Early Farmers

When the climate gradually warmed up after approximately 9,000 years ago, some societies living in the southern edge of the Inner Mongolia, the middle and lower reaches of the Yellow and the Yangzi River valley began to cultivate millets and/or rice, respectively. Grains of broomcorn and foxtail millets have been found in the Xinglonggou site in Inner Mongolia, the Cishan and Peiligang sites in the middle Yellow River Valley, the Yuezhuang site in the lower Yellow Valley, and the Dadiwan site in the upper Yellow River Valley, all dated to between 9,000 and 7,500 years ago (Fig. 1). It has been argued that the millets are domesticated except the grains found in Yuezhuang, which cannot be confidently identified (Lu 1999; Crawford 2011; Zhao 2011). Rice grains have been found in the Jiahu site in the Huai River Valley dated to between 9,000 and 7,800 years ago, in the Pengtoushan and Bashidang in the middle Yangzi Valley dated to about 9,000–7,500 years ago, and in the Shangshan site in the lower Yangzi Valley dated between 10,000 and 7,500 years ago (Fig. 1). According to Zhao (2011), the rice grains found in Jiahu are likely to be domesticated, but the species of the Shangshan rice is unclear. Rice grains found in Bashidang are probably in between wild and domesticated and are identified as a transitional species (Zhang 1998).

Northern Asia: Origins and Development of Agriculture,
Fig. 1 Archaeological sites mentioned in the text: *1* Xianrendong/Diaotonghuan; *2* Yuchanyan; *3* Zengpiyan; *4* Xiachuan; *5* Xinglonggou; *6* Cishan; *7* Peiligang; *8* Yuezhuang; *9* Jiahu; *10* Yangshao; *11* Dadiwan; *12* Pengtoushan/Bashidang; *13* Shangshan; *14* Kuahuqiao; *15* Hemudu; *16* Chengtoushan; *17* Xinle; *18* Krounovka 1; *19–20* Pyeonggeodong and Tongsamdong; *21* Archaeological sites of the Yayoi culture; *22* Nan-kuan-li

Although living in different environments and cultivating different cereals, the cultivators of millets and rice shared some cultural similarities. First of all, they are all sedentary, as remains of houses have been found in all the aforementioned sites. Experiments of millet and rice cultivation indicate that sedentism is a crucial condition for cereal farming (Lu 2006), and the construction of houses results from sedentism. However, houses not only are shelter for human beings, but also provide space and facility for the formation of small social units (family?) and the storage and accumulation of private or family-owned properties, which eventually leads to private properties and social inequality, although archaeological data of the early farmers do not illustrate significant gap between households at this stage (Lu in press). Second, hunting and gathering (including fishing) remained as important subsistence strategies of the early farmers, illustrating that the origin and development of agriculture is a graduate process in Northern Asia, and that foraging did not immediately diminish after the occurrence of farming (Lu 2006). In fact, it is the development of agriculture, sedentism, increased population and much greater demand for wild plant and animal resources that eventually led to the depletion of wild flora and fauna, thus forced farmers to reduce foraging and rely more on agriculture (Lu in press). Thirdly, based on pottery and stone tool analysis, labor division and craftsmanship are at a very early stage in the early farming society (Lu in press). Finally, burials have been found in all the aforementioned sites except Shangshan, and items such as tortoise shells have been found in Jiahu, manifesting the existence of cognitive sense of social unit and the possible practice of rituals (Lu in press).

Did the early farmers keep livestock? Genetic studies suggest that dog might have been domesticated in East Asia, and the earliest one might have been found in northern China dated to about 10,000–9,000 years ago, but there is no evidence that the dog keepers were farmers. The dog found with millet cultivators in the Dadiwan culture is dated to between 8,000 and 7,400 years ago (Flad

et al. 2009). The earliest domesticated pig was kept by the Jiahu rice farmers dated to approximately 8,500–7,800 years ago, and at around 8,100–7,400 years ago pig might have been husbanded by farmers at Xinglongwa in Inner Mongolia, Dadiwan in the upper Yellow River Valley, Cishan in northern China, and Kuahuqiao in the lower Yangzi River Valley (Flad et al. 2009) (Fig. 1). Sheep and goat are not locally domesticated, and might have been introduced into China by about 5,600–5,000 years ago; so would be the case for cattle, although the domestication of cattle in East Asia cannot be ruled out, as wild cattle exist in this region (Flad et al. 2009).

The Development of Agriculture

The Holocene climatic optimum between approximately 7,000 and 4,500 years ago witnessed the development of agriculture in Northern Asia, characterized by the occurrence of paddy rice field and plowing in the Yangzi River Valley, and sophisticated craftsmanship in both the millet and rice farming societies. Socially, this is an era of more stable sedentism, larger settlements, branched social units within the village, different economic and social status among members of the society, and gender differentiation (Lu 1999, in press).

This period also saw the expansion of agriculture possibly associated with human diaspora. Rice farming dispersed northward to the Yellow River Valley at about 7,000 years ago, and southward to South China by 6,500 years ago; and millet farming expanded to Xinle, Northeast China at around 6,100 years ago (Lu 2005) (Fig. 1). The number of archaeological sites with remains of millets and/or rice increased substantially, the size of many sites became bigger, and the impact of agriculture upon local environment and natural resources was also visible in this era. For example, in the Hemudu site (Fig. 1), Zhejiang Province, China, where substantial amount of rice remains were found in the 1970s, pollen profiles indicate that the quantity and variety of hardwood was very rich at around 7,000 years ago when the rice farmers arrived; however, both the quantity and variety of hardwood reduced significantly at around 6,000 years ago, after the site being occupied by farmers for about 1,000 years, clearly showing the impact of farming activities upon local vegetation (Lu in press). Vegetation changes will have impact on local fauna. The quantity and variety of animal bones found in many archaeological sites occupied by millet and/or rice farmers between approximately 7,000 and 4,500 years ago also show the trend of declining (Lu 2006, in press).

After 7,000 years ago, rice and millet farming further expanded to Russia, Taiwan, the Japanese Archipelagos, the Korean Peninsula, Southeast Asia, and the Pacific. Within Northern Asia, seeds of broomcorn millet and beefsteak plant have been found in the Krounovka 1 site dated to between 4,670 and 4,640 years ago in Primorye, Russia; wheat, barley, pea, soybean, and buckwheat have been found in various archaeological sites dated after about 5,000 years ago, and hoed agriculture occurred at around 4,500 years ago in this region (Kuzmin and Rakov 2011) (Fig. 1). Dog was the earliest domesticated animal in Russia Far East dated from about 6,800 years ago, and animal husbandry began at around 3,000 years ago, with domesticated pig, horse, and cattle (Kuzmin and Rakov 2011).

In the Korean Peninsula, no archaeological data on prehistoric agriculture is available in North Korea (Lee 2011). The earliest remains of foxtail and broomcorn millet and legumes in South Korea are found in Tongsamdong and Pyeonggeodong (Fig. 1), dated to about 5,500 and 5,000 years ago; rice remains are dated to between approximately 4,000 and 3,000 years ago, and domesticated dog occurred at about 5,500–4,000 years ago, while remains of domesticated horse and cattle are dated to about 2,300 years ago (Lee 2011). Foxtail millet and rice farming reached Nan-kuan-li, western Taiwan by 4,500 years ago (Tsang 2005). Wet-rice farming expanded to the Japanese Archipelagos in the Yayoi period at around 2,800 years ago, and became a major subsistence strategy afterward (Misaka and Wakabayashi 2011) (Fig. 1).

Domesticated species from far afield also entered Northern Asia after approximately 5,000 years ago, most noticeably wheat and barley, which are originally domesticated in West

Asia at around 10,000 years ago (Bellwood 2005) and expanded to Russia Far East (Kuzmin and Rakov 2011), the Yellow River Valley and adjacent areas by about 4,300–4,000 years ago (Zhao 2011). In other words, by 2,800 years ago, the cultivation of local species of rice and millets was practiced in continental and island Northern Asia, and "exotic" species like wheat and barley had also cultivated in the cold and temperate eco-zones.

Agriculture of Other Plants

The aforementioned archaeobotanic data are primarily retrieved by flotation and phytolith analysis, which have been applied quite extensively in archaeological works conducted in Northern Asia after the 1980s. However, not all plant remains can be identified by the two methods, particularly tuber plants, which produce no phytolith, and cannot be identified to genus or species based on their charcoal remains found in archaeological deposits. Thus in recent years starch residue analysis has also been used in archaeological works in Northern Asia. In 2003, starch residues of taro were found on tools in the Zengpiyan cave site in Guangxi, South China, but starch cannot reveal whether it is a wild or domesticated species (Lu 2008) (Fig. 1). This study shows the exploitation of taro in South China before the expansion of rice farming from the Yangzi River Valley, but it is unclear whether South China is another independent center for the origin and development of taro farming (Lu 2008).

In addition to cereals and tubers, many other plants have been exploited and possibly cultivated in Northern Asia. The Jomon people lived in Japan between 12,000 and 3,000 years ago collected and utilized many plants, including chenopods, dock, knotweeds, elderberry, grape, lacquer tree, goosefoot, walnut, beans, bottle gourd, hemp, and barnyard grass *Echinochloa crus-galli*, the latter might have been cultivated afterward (Crawford 2011). Based on genetic studies and archaeological data, it is also hypothesized that azuki and soybean might have been domesticated in Japan by the Jomon people, as well as by the Chulmun people in South Korea at around 5,300–5,000 years ago (Crawford 2011; Lee 2011), but more data are required to address these hypotheses.

Key Issues and Current Debates

Though many works have been done in the last decades, there are still issues under debate. These issues can be classified into two categories: the first one on the identification and classification of raw data, and the second one on the theoretical discourse of agriculture, such as the impetus, process and consequence of agriculture, and whether agriculture is an "advanced" development.

The Identification and Classification of Raw Data

Within this category there are debates on the progenitors of broomcorn millet and domesticated rice, as botanists and genetics still do not know much on the former, and disagree on the latter. Some scholars argue that the perennial wild rice (*Oryza rufipogon* Griff.) should be the progenitor, but others think that it should be the annual wild species (*O. nivara* Sharman and Shatry). While one subspecies of domesticated rice (*Oryza sativa japonica*) seems to have been domesticated in the Yangzi River Valley, it remains unclear where, when and by whom the other subspecies *O. sativa indica* and *O. sativa javanica* were domesticated. It is also unclear whether soybean was domesticated in Northeast China once, or was also domesticated in Korea and Japan (Crawford 2011; Lee 2011).

The question of when and how domesticated wheat, barley, and sorghum were introduced from Western Asia into Northern Asia also requires further studies (Zhao 2011). In addition, very little is known about the cultivation and domestication of many other plants, such as the Chinese tea tree, jujube, peach, lotus, water chestnuts, Chinese cabbage, and other species of vegetables, fruits, and nuts in Northern Asia (Lu 1999, in press; Crawford 2011; Kuzmin and Rakov 2011; Lee 2011).

In terms of identifying archaeobotanic findings, scholars also disagree on whether the morphological differences and measurements of rice

grains and spikelet bases, as well as the phytolith morphology of the husks and leaves of rice, can be used to distinguish wild and domesticated rice (Lu 2006, in press). As domestication is a process, there should be species in-between (Zhang 1998). Based on comparative measurements of the perennial wild rice (*O. rufipogon* Griff) and domesticated rice (*O. sativa japonica*), it is argued that a more holistic approach is required, as the size and structure of the stem and spikelet of the two species also differ and should be taken into consideration (Lu in press). Further, how to be certain that plants and animals found in archaeological sites were locally cultivated/husbanded, instead of being brought to the site as a result of cultural exchange and trading, is an important issue too (Lu 2008, in press; Crawford 2011).

There are more remaining questions on the husbandry of animals in Northern Asia. As mentioned above, the domestication of cattle, chicken, water buffalo, silkworm, and fish remains unclear to date, as scholars are debating on the identification of wild and domesticated species of cattle, chicken, and water buffalo (Flad et al. 2009; Kuzmin and Rakov 2011), and very little attention has been paid to the cultivation of silkworm and fish in Northern Asia.

Theoretical Issues

To date, the majority of scholars working on agricultural in Northern Asia agree that the origin and development of agriculture is a process, but there are different opinions on defining "agriculture," on the causal factors of the transition from foraging to farming, on the impact of cultural contact between the Yellow and the Yangzi River Valley related to the origin of agriculture, as well as the consequence of agriculture (Lu 1999, 2006; Crawford 2011; Kuzmin and Rakov 2011). Data of archaeology and other disciplines are far from sufficient to solve these debates at the present, but the consequence of agriculture seems to be very significant.

Based on archaeological, archaeobotanic, and zooarchaeological data found in Northern Asia to date, plus data from collecting, cultivation, and harvesting experiments, it is argued that when cereal cultivation began in the Yellow and the Yangzi River Valley, the productivity must be very low, particularly for rice, as the progenitor of domesticated rice is a perennial plant and produces very small amount of shattered seeds; thus, harvesting wild rice as food is highly inefficient comparing to collecting tuber plants, shells, and fishing (Lu 1999, 2006). Given the extremely low or even negative return of cultivating wild cereals at the initial stage of farming, agriculture must have been a small proportion of prehistoric economy, and it is possible that the main driving force for continuous cereal cultivation might not have been for food, although whether religious or other cognitive activities playing any role in this process requires further studies (Lu 2006, 2008, in press).

However, once occurred, cereal cultivation has significant impacts on people's way of life. First of all, it requires sedentism in order to look after and harvest the plants. Second, it requires close access to substantial amount of water and flat land. These requirements must have forced the initial cultivators to give up caves in hilly areas and move to plains and river terraces. Consequently, they had to learn to build dwellings, which was the beginning of architecture and settlement planning of human beings. Archaeological data have illustrated this change of settlement patterns in the Yangzi and Yellow River Valleys, as the prehistoric farmers are often located in the latter geographic settings (Lu 1999, in press).

Dwellings are not just for the physical protection and comfort of people. Based on ethnographic and archaeological data, it is argued that when a group of mobile people staying in caves, members of the group had to share *one* public and unstable space; there was no permanent and private space for them to keep and accumulate private properties. However, sedentism and the construction of dwellings provide stable and private spaces for people to store and accumulate their private properties, thus facilitate the occurrence and development of private (as individual or small social unit) ownership and inheritance of properties, which could be tangible items like tools, pottery, food (including the storable cereal grains), etc., or intangible items like craftsmanship and knowledge. All these have paved the way

for social inequality (Lu in press). Studies on the dynamic between agriculture, changed space structures and social changes in prehistoric Northern Asia are quite limited at the moment, and much more research is required.

As agricultural techniques developed, particularly with the construction of paddy field for rice farming as a powerful medium of human interference by around 7,000 years ago, wild cereals were gradually domesticated, farming productivity might have increased, and more mouths could be fed. On the other hand, ethnographic and historic data demonstrate that traditional agriculture (without machines) is very labor intensive, thus more hands would be required. These factors, plus sedentism, must have led to population increase, as illustrated by the significantly enlarged settlements, increased houses within each settlement, and more densely located settlements in the Yellow and Yangzi River valley, as well as in adjacent areas (Lu 1999, 2006, in press). However, much more research is required on the impact of technological changes upon demographic, economic, and social change, as it is another important theoretical issue in prehistoric Northern Asia.

With all the aforementioned material culture, economic and social changes, labor division, professionalization and standardization of craft production, increase economic, social, and political inequality gradually occurred after 7,000 years ago. As increased populations had to compete for limited land and water resources, group conflicts occurred or increased, and walled villages, and later, towns, were constructed. The earliest protective ditches surrounding a farming village have been founded in Bashidang, the middle Yangzi River Valley, dated to about 8,500–7,800 years ago (Fig. 1); and the earliest walled town has also been found at Chengtoushan in the same region dated to approximate 6,500–6,300 years ago, with rice paddy field being enclosed by the wall (Lu in press) (Fig. 1). This phenomenon clearly demonstrated that, first of all, rice field was a valuable property of the farming society at that time. Although it is not clear whether the field was publicly or privately owned, the protected rice paddy field illustrates the occurrence of immovable properties (farming land) and territory ownership in prehistoric Northern Asia. Second, the construction of these protective mechanisms indicates that there might have been group conflicts related to crops and lands. Further, these protective mechanisms are material evidence of the existence of some kind of cognitive boundary between social groups, even collective identities (Lu in press). The occurrence of individual and collective identity is a topic of cognitive archaeology and anthropology, and more attentions are deserved on this topic in Northern Asia.

More walled towns occurred in both the Yellow and the Yangzi River valleys after 6,000 years ago, particularly at around 4,800–4,000 years ago. At that time, farming techniques had developed further, rice paddy fields with irrigation system were constructed, plough was used in the Yangzi River Valley, and hoe was widely used in the continent of Northern Asia. The period between approximately 5,000–4,000 years ago saw further increased productivities and populations, accumulated tangible and intangible properties, more specified labor division and professionalization not only within the same group but between regions, and mass production of certain crafts, like pottery items, in the Yangzi River Valley. There were small and big houses within farming societies, and the quantities and qualities of burials in cemeteries varied significantly. Labor-intensive items for the social elite like jade and ivory items appeared in some of the big tombs located at human-made mounds in the lower Yangzi River Valley, possibly used for rituals and other special functions. All these illustrate the occurrence of complex society, with substantially differentiated social segments. It is based on this kind of society that ancient civilization in the Yellow River Valley occurred after 4,000 years ago (Lu in press). The formation process from complex societies to early states in Korea and Japan, on the other hand, is not very clear yet (Stark 2006).

Based on available data to date, the development of agriculture was associated with the decline of both the quantity and variety of wild plants and animals found in many archaeological sites in both the Yellow and the Yangzi River

Valley after approximately 6,000 years ago, particularly after 4,500 years ago (Lu in press). As the climate between 7,000 and 4,000 years was generally warm and moist, it is more likely that this decline was the result of human activities and increased consumption of human populations in the two river valleys, which had been intensively farmed since some 9,000–8,500 years ago. Eventually, it became more difficult for members of the farming societies to hunt and collect, and they had to rely more on a few species of cultivated cereals and livestock (Lu in press). Foraging became less important and agriculture was more dominating in the economy. The diminishment of a broader spectrum subsistence strategy not only means that human beings have been irreversibly "domesticated," that their way of obtaining food becomes more vulnerable when attacked by natural and human-made disasters, but also means that it is more difficult for the poor members of the society to obtain free food from nature (Lu in press). The lack of variety of food ingredients, particularly the insufficient meat intake, might have caused malnutrition of the lower social class, although much more physical anthropological studies of human bones are required to tackle this issue. However, historic documents show that the upper class in Bronze Age Yellow River Valley was called "meat eaters" as opposite to the grass-root people (Lu in press). Thus, the development of agriculture, and consequently the depletion of natural resources, has widened the gap between different social segments in terms of not only economic, social, and political status, but also physical well-being.

On the other hand, archaeological data and isotopic analysis seem to indicate that fishing, shell collecting, and foraging still played important roles even after the occurrence of farming in coastal and inland societies from approximately 5,500–3,000 years ago in South Korea, where intensive agriculture occurred by 3,400 years ago, possibly associated with migrating farmers from the Northern Asia continent (Lee 2011). Whether the less intensified agriculture in South Korea produced less impact on the environment and depletion of wild fauna and flora, requires further studies.

In summary, the origin and development of agriculture in Northern Asia some 9,000–8,000 years ago (Two articles published in PNAS and PLoS by Lu et al. (2009) argue that foxtail millet was domesticated in the Yellow River Valley by 10,000 years ago. However, the majority of scholars, working on prehistoric agriculture, including the author of this entry, do not agree, because the site was not re-excavated, and the archaeological context is not clear. For details please see Zhao (2011) in the reference list of this article.) have caused fundamental changes in terms of human beings' mobility, subsistence strategies, social (including kinship) and political structures, as well as their physical beings and mindsets, including the senses of property and territory ownership, and group boundary. It is primarily based on agriculture of millets, rice, wheat, and barley that ancient civilizations occurred in the Yellow River Valley by about 4,000 years ago and in the Japanese Archipelagos and the Korean Peninsula after 2,000 years ago (Lu 1999, 2006; Crawford 2011; Lee 2011; Zhao 2011). Agriculture was the choice made by some groups in Northern Asia at the beginning of the Holocene, and it has sent human beings onto a completely new trajectory with no return.

As agriculture sets the foundation of civilization, archaeologists in mainland China tend to think agriculture is an "advance," and blame environmental changes for the decline of some farming societies in the Yangzi River Valley, while scholars outside mainland China have different opinions (i.e., Lu 2006, 2008; Crawford 2011; Lee 2011). It has been argued that the current definition of "agriculture" is a Eurocentric concept (Crawford 2011), but the concept of "agriculture" in China also has a long history in the academic discourse in the Central Plain of the middle Yellow River Valley, which has been the "core area" of Chinese civilizations (Lu 1999, in press), so it really is a "Central-plain centrism" concept versus the foraging groups living in the so-called peripheral areas in China, the latter have been often described as "barbarians" and/or "backward" in China's historic documents and even the current archaeological discourse. Thus, the debate of whether agriculture is an "advance"

or is the biggest mistake made by human beings is about whether cultural changes are unilinear or multilinear, about cultural relativism *versus* cultural "evolution," about Sinocentrism and/or "Central-plain centrism" *versus* cultural diversity in areas other than the so-called core areas of the origin of agriculture, and about using the past to construct and enhance nationalism and patriotism of different polities in Northern Asia today.

International Perspectives

There are the so-called core and secondary regions in terms of the origin and development of agriculture in Northern Asia, each showing various trajectories of cultural changes from approximately 15,000 to 3,000 years ago. A comparative discussion within Northern Asia can trigger questions on the diversity of human beings and environments, as well as their unique cultures (Crawford 2011). Further, the analytic outcome from Northern Asia can also be compared with those in Southeast Asia, where rice farming occurred at approximately 4,700–4,000 years ago (Bellwood 2005). The origin and development of agriculture might have resulted in human diaspora within Asia and from Asia to the Pacific, particularly the expansion of the Austronesians and Austroasiatics, which has contributed to the current distribution of human beings in the world (Bellwood 2005).

Data found in Northern Asia to date do illustrate similarities and differences in terms of the transition from foraging to farming comparing to the origin and development of agriculture in Western Asia, which is the earliest core area of the origin and development of agriculture. With insufficient data dated to about 12,000–10,000 years ago in the Yellow and the Yangzi River Valley, it may be premature to launch a comprehensive comparison on the two "primary centers" of agriculture; but this comparison certainly will provide fundamental insights for understanding the dynamics between peoples and different natures, the unilinear or multilinear development of human cultures and societies, the inter- and intragroup interactions as one of the crucial mechanisms of cultural changes, and the creativeness of human beings as "agents" (Lu 2006, in press). Finally, the study of the origin and development of agriculture also provides lessons from the past for the present and future of humans' destinations.

Future Directions

As mentioned above, there are still many questions remaining on the origin and development of agriculture in Northern Asia. To tackle the issues, it is important to:

1. Adopt integrated multidisciplinary studies to retrieve as much information as possible at field work, such as the integration of isotopic, residue, phytolith, pollen, and use-wear analysis of archaeological findings.
2. Integrate archaeological experiments with archaeological data and information from other disciplines to understand the evolution process from wild to domesticated species and its impacts on human/cultures.
3. Apply theories of anthropology, critical geography, and sociology to study the dynamic and consequence between material culture, social, and politic institutions and cognitive changes, for example, the function and meaning of spaces in prehistoric societies or the occurrence of individual and collective identities.
4. Conduct research with scholars from different countries within and outside Northern Asia to facilitate comparative studies. In fact, this is already happening now, but it will benefit the whole field of prehistoric agriculture if this international and multidisciplinary approach becomes more common in Northern Asia.
5. Increase academic exchanges by timely publications in various languages, and by more academic meetings, site visiting, and workshops.
6. Train the younger generation with broader knowledge. Students major in archaeology should also receive introductory training on genetics, phytolith, pollen, archaeozoology, and theories of anthropology. A more in-depth and holistic study on the origin and

development of agriculture in Northern Asia can only be carried forward by scholars with broaden academic horizon.

In summary, works carried out by archaeologists, archaeobotanists, historians, zoologists, and scholars of many other disciplines in the last decades have set a solid foundation for understanding the origin and development of agriculture in Northern Asia. It is believed that with new technologies, new methods, and new mindsets, much more data will be revealed, and the whole process from foraging to farming, as well as the consequence of this transition in Northern Asia, will be much better understood, and provide food for thoughts for humans at the present and in the future on the relation between human and nature and between human cultures, as well as on the direction of human societies as a whole.

Northern Europe: Middle to Upper Paleolithic Transition

Damien Flas
Archéologie préhistorique, Université de Liège, Liège, Belgium

State of Knowledge and Current Debates

Introduction

Seen from Europe, it has been often claimed that the beginning of the "Upper Palaeolithic," around 40,000 BP, corresponds to a dual phenomenon: the development of innovative behaviors and a biological change (the disappearance of the last Neandertals and the arrival of *Homo sapiens sapiens*). These different behaviors seen as particular features of the Upper Palaeolithic (see, among others, Mellars 1989) include, for example, lithic tools based mostly on blade production, a greater variety and increased standardization of tools, bone tool production, ornaments, figurative art, greater regional variety in lithic industries and more rapid evolution through time, the existence of systematic and specialized hunting (as opposed to scavenging and opportunistic hunting that was previously more common), demographic increase, increase in the size of occupation areas, and development of dwelling structures, etc. Other criteria have also been sometimes proposed as markers of the Upper Palaeolithic, such as bladelet production (Bar-Yosef and Kuhn 1999).

Trying to escape from a definition of the Upper Palaeolithic based on European data and given the numerous evidence of so-called "Upper Palaeolithic" behaviors during the African Middle Stone Age, the "behavioral modernity" concept has been increasingly employed, being now as important as the concept of "Upper Palaeolithic" itself. However, this concept remains fuzzy; material traces of such "behavioral modernity" are not so easy to identify in the archaeological record and often correspond to the same list of behaviors (bladelet production, ornament, bone tools, etc.). But other phenomena have also been claimed to correspond to this "behavioral modernity," among others: funerary practices, sailing (involved in the peopling of Australia), rocks or bones with organized incisions, musical instruments, projectiles and other composite tools, use of pigments, planning depth in the management of raw material procurement, and the existence of exchange networks (see, e.g., McBrearty and Brooks 2000).

Whether using the concept of "Upper Palaeolithic" or of "behavioral modernity," scholars often propose to attribute these different innovative behaviors to a cognitive evolution unique to anatomically modern humans (different from the other hominins, whether Neandertals, Denisovans, or *Homo erectus*) (e.g., Mithen 1994). This model linking biological evolution and cultural changes has two variants: some scholars propose the existence of rapid and recent cognitive change (after 50,000 BP; e.g., Klein 2000), others propose slower and gradual evolution, more ancient (transition between Acheulean and *Middle Stone Age*, between 300 and 200,000 BP) unique to Africa where such "behavioral modernity" would develop in parallel with the modern anatomy of *Homo sapiens* (McBrearty and Brooks 2000). In both cases, it is then proposed that the development of the Upper Palaeolithic in the different regions of the world can be explained by the dispersal of anatomically modern humans from Africa and the Near East (in agreement with most of the palaeoanthropological and palaeogenetic hypotheses). Thus, the beginning of the Upper Palaeolithic in Europe and Asia would be strictly related to the spread of *Homo sapiens sapiens* replacing other hominins (Mellars 2006; McBrearty and Brooks 2000; Bar-Yosef 2007; Hublin 2015) even if a certain amount of admixture has now been established between different hominin populations in Eurasia based on genetic data (Prüfer et al. 2014).

Another general model proposes, on the contrary, that Upper Palaeolithic development is not related to the replacement of archaic populations by a "modern" one and that the Middle to Upper Palaeolithic transition does not correspond to a particularly deep behavioral shift (Clark 1999; Straus 1995). This transition is considered as a step during a longer and gradual evolutionary process, where selection and adaptation (notably

due to environmental changes) are the driving forces of the progressive transformation of cultural and behavioral choices. Regarding biological evolution, this "continuity" model was related to work by palaeontologists defending the idea of a multiregional origin of modern *Homo sapiens* rather than dispersal and replacement from a unique African source (e.g., Wolpoff et al. 2001) that has now been abandoned notably because of the accumulation of genetic data (e.g., Fu et al. 2016).

However, these two conceptions of the development of the Upper Palaeolithic, one in which it is seen as a "package" of behaviors unique to anatomically modern humans who spread across the globe with the dispersal of this new population, and the other in which the shift from Middle to Upper Palaeolithic is just a step among others during universal and progressive evolution, both show weaknesses that should lead to the development of more complex approaches of these issues.

Indeed, numerous discoveries and recent research show that at least some of the behaviors said to be "modern" were already present before the Upper Palaeolithic and even outside the African Middle Stone Age and *Homo sapiens sapiens* populations. Cynegetic capacities (e.g., Rendu et al. 2012); hafted tools and projectile points (Rots 2013; notably involving synthetic resins: Grünberg 2002), planning depth in the management of the lithic resources (Roebroeks et al. 1988), spatial organization of the living areas (e.g., Speth 2006), funerary practices (Rendu et al. 2014), use of bone tools (Soressi et al. 2013), and use of pigments and presence of rocks and bones with organized incisions (Soressi and d'Errico 2007) are all attested during the Middle Palaeolithic of Eurasia, notably among Neandertals.

Moreover, the artificial nature of the package of new behaviors, said to be unique to the Upper Palaeolithic or to "behavioral modernity," is also visible because it groups phenomena that developed independently at different times and in different regions. Ornaments, figurative art, or bone tools did not appear at the same time in the same regions with the presence of anatomically modern humans. The idea that it is possible to follow a dispersal of anatomically modern humans across the globe that would correspond to the development of the Upper Palaeolithic is not supported by the archaeological record.

Behind the so-called "Middle to Upper Palaeolthic transition" are thus hidden a large variety of different phenomena, and it is better to tackle them separately to be able to draw more precisely the history of the human societies during this particular period.

Related to this strongly debated issue, the European Aurignacian and "transitional industries" draw much attention to technological, behavioral, and chronological aspects. However, some regions, like North-Western Europe, and various technocomplexes, are still poorly known and often neglected when broad-scale views of this period are proposed. Concerning the North-Western Europe "transitional industry," called the Lincombian-Ranisian-Jerzmanowician (LRJ), it is nonetheless possible to integrate this region into discussions of the transitional period, concerning both cultural change and the question of the anatomy of the hominins involved, the last Neanderthals or first European *Homo sapiens sapiens*.

The Issue of the Lincombian-Ranisian-Jerzmanowician Definition: A Short History

Leaf-points made on blade blanks by partially bifacial retouch, now for the most part called "Jerzmanowice points," were discovered at several sites during pioneering nineteenth-century excavations in Great Britain, Belgium, Germany, and Poland. At that time, they were compared to the Solutrean and Protosolutrean industries. Henri Breuil (1912) described these artifacts as "Protosolutrean features," and this attribution persisted until the second half of the twentieth century (e.g., Garrod 1926). Later, some researchers (Sonnevilles-Bordes 1961) suggested an earlier age for these artifacts, and this was confirmed by the first radiocarbon dating of Nietoperzowa Cave, layer 6 (Poland) that led Waldemar Chmielewski (1961) to define the "Jerzmanowician," based mainly on the three layers (6–4) yielding blade leaf-points that he recognized during his excavations in this cave.

The Protosolutrean nature of the Jerzmanowice points from Great Britain and Belgium was later questioned, notably after the publication of Ranis Cave (Thuringia, Germany; Hülle 1977) where a layer yielding similar artifacts was found between Middle Paleolithic and Aurignacian layers, confirming the early age of this assemblage with Jerzmanowice points. In Great Britain, works by Roger Jacobi (1980) and John Campbell (1980) led to the definition of the "Lincombian," also marked by the presence of Jerzmanowice points. Finally, given the strong similarities of the leaf-points from these adjacent regions (Otte 1981), these different geographically limited names were combined into the "Lincombian-Ranisian-Jerzmanowician complex" (Desbrosse and Kozłowski 1988; here shortened to LRJ).

The definition of this new technocomplex has nonetheless often been rejected. The relevant assemblages being rare and poor, the characteristic artifacts having been often found mixed with other industries during imprecise excavations, it seemed more relevant to some researchers to not isolate these small assemblages within a separate technocomplex, but rather to consider these artifacts as part of already defined complexes. The Jerzmanowice points have thus been sometimes associated with the Aurignacian, in Great Britain and Belgium, and to the Szeletian in Central Europe (e.g., Allsworth-Jones 1986), or even to the Bohunician (Svoboda 2004: 43), as a hunting camp facies or as an economic facies (related to the availability of lithic raw material) of these complexes.

The Lincombian-Ranisian-Jerzmanowician

Geography and Chronology

Excluding dubious assemblages (lacking diagnostic artifacts), the LRJ complex has been identified at 41 sites (including isolated artifacts, sometimes from surface collections; Flas 2008). Most of them (32) are found in Great Britain (Jacobi 2007), assemblages from continental Europe (Belgium, Netherlands, Northern Germany, and Cracovian Jura) being clearly less numerous (Fig. 1). Even if the Jerzmanowice points from Czech sites are added, for which chronocultural attributions are debated (Nad Kačákem and Pekárna Caves, surface collections from Dubicko, Ondratice and the Brno region; Flas 2008), the difference between Great Britain and the continent is still significant and cannot be explained as a mere consequence of the history of Paleolithic research in these different regions.

All of the stratified LRJ assemblages (33) come from Interpleniglacial (Isotopic Stage 3) deposits. For a more precise view of the chronological situation of the LRJ, the available data are, however, rare. At Ranis, the LRJ assemblage (Ranis 2) was found in a layer between an underlying Late Middle Paleolithic (*Blattspitzengruppe*, Ranis 1) and an overlying Aurignacian level (Ranis 3; Hülle 1977). This position between the Middle Paleolithic and the Early Upper Paleolithic is also indicated by the LRJ assemblages that have been mixed with both Mousterian and Aurignacian (and/or Gravettian) artifacts during ancient excavations (e.g., Paviland, Hyena Den, Kent's Cavern, Pin Hole, Spy, Goyet; Flas 2008).

Since the development of radiocarbon techniques, many results have been used to date assemblages with Jerzmanowice points. However, after a critical review, very few of these dates can be considered as relatively reliable. Indeed, imprecision during ancient excavations, as well as reworked and obviously mixed assemblages, makes associations between the dated samples (most of the time bones without anthropic traces) and the LRJ artifacts from the same deposits (Flas 2008) quite dubious.

It is, at any rate, possible to use the few dates that give the most reliable indications. Layer 6 from Nietoperzowa Cave yielded two ^{14}C dates around 38,000 BP (uncalibrated), consistent with the site stratigraphy. Recently, more radiocarbon dates confirmed the age of this layer between 37 and 40,000 BP (uncalibrated) (Krajcarz et al. 2017).

Recently, at Glaston (England), six ^{14}C dates using ultrafiltration, made on bones directly associated with a recently excavated open-air LRJ occupation have confirmed an age around 38,000 BP (Cooper et al. 2012). These are at present the most reliable results available for the LRJ complex.

Northern Europe: Middle to Upper Paleolithic Transition, Fig. 1 LRJ sites (circle: open-air site; triangle: cave site; illustration: Jerzmanowice point from Spy cave; redrawn after Otte 1979). 1-Paviland, 2-Ffynnon Beuno Cave, 3-Bench Tunnel Cavern, 4-Windmill Hill Cave, 5-Kent's Cavern, 6-Uphill Quarry Cave 8, 7-Soldier's Hole, 8-Hyeana Den, 9-Badger Hole, 10-King Arthur's Cave, 11-Pin Hole, 12-Robin Hood Cave, 13-Glaston Grange Farm, 14-Beedings, 15-Earl of Dysart's Pit, 16-Drayton, 17-Warren Hill, 18-White Colne Pit I, 19-Eastall's Pit, 20-Bramford Road Pit, 21-Moordown, 22-Sutton Courtenay, 23-Osney Lock, 24-Creffield Road, 25-Wallow Camp, 26-Brandon, 27-Town Pit, 28-Bapchild, 29-Conningbrook Manor Pit, 30-Hainey Hill, 31-Goldcliff, 32-Temple Mills, 33-Aardjesberg, 34-Spy, 35-Goyet, 36-Zwergloch, 37-Ranis 2, 38-Grotte Nietoperzowa, 39-Grotte Koziarnia, 40-Grotte Puchacza Skała

Some other British sites have yielded similar results, between 38,000 and 36,000 BP. Nonetheless, these dates should be considered with caution, given the quality of early excavations and the nature of the deposits yielding the Jerzmanowice points and the dated bones found near them (Jacobi 2007).

While the development of the LRJ around 38,000 BP (or ca. 43,000 BP calibrated) is thus likely, the chronology of the end of this complex is more difficult to determine. Beedings, an important LRJ open-air site of South-East England, yielded a later TL date, but with a large sigma, and is considered a minimum age for the occupation (Jacobi 2007). There is only one date indicating a possible extension of the LRJ, around 30,000 BP, but it was obtained on a bone (not humanly modified) of imprecise provenience (layer 5 or 4?) from Nietoperzowa Cave. Thus, given the available chronological data, the LRJ does not seem to have existed later than 35,000 uncalibrated BP (Flas 2008).

Main Features of the LRJ Lithic Industry

Jerzmanowice points being the *fossile directeur* (and thus the most easily identifiable LRJ artifacts in mixed assemblages and in collections lacking stratigraphic context), and perhaps also due to the cynegetic function of most of the known LRJ occupations, they are the most commonly found type of tool (Figs. 1 and 2). On average, they have a length around 9–10 cm, width of 3 cm and thickness of 1 cm. However, these points show some diversity, particularly variability in size and in the extension of retouch, but such subtypological variety cannot be correlated with geography nor can it be explained by development from sturdier to lighter (gracile) points as proposed by Waldemar

Northern Europe: Middle to Upper Paleolithic Transition, Fig. 2 Jerzmanowice points. 1: Beedings (after Jacobi 2007); 2: Kent's Cavern; 3: Robin Hood Cave; 4-5: Spy Cave (6 after Flas 2008); 6: Ranis 2 (after Hülle 1977); 7: Nietoperzowa cave

Chmielewski (1961). The variability of the Jerzmanowice points seems more likely related to properties of the blades that were used (dimensions, presence of cortex, more or less straight morphology) and, in rare cases (notably for the LRJ assemblage from Spy cave), to the reduction process of such pieces (Flas 2008).

No use-wear study has ever been made on Jerzmanowice points. Nonetheless, these pieces being pointed and symmetric, and likely axially hafted as suggested by the importance of proximal shaping (by inverse flat retouch and sometimes dorsal longitudinal thinning; Fig. 2, no 2), as well as likely impact fractures (burin-like removals,

"spin-off" removals, strongly marked bending fractures) seen on some of them (notably in the Beedings assemblage; Jacobi 2007; Fig. 2, no 1), support the hypothesis of use as projectile points.

In addition to Jerzmanowice points, LRJ assemblages may also contain bifacial leaf-points, made on blocks or large flakes (Fig. 3). They are far less numerous than the former, except in the Ranis 2 assemblage (Hülle 1977), and are only found in a few sites (Paviland Cave, Kent's Cavern, Soldier's Hole, Robin Hood Cave, Bramford Road, Nietoperzowa Cave).

Northern Europe: Middle to Upper Paleolithic Transition, Fig. 3 Bifacial leaf-points. 1: Robin Hood Cave (after Jacobi 2007); 2: Ranis 2 (after Hülle 1977)

Other tool types are much less common (Flas 2008; Fig. 4). However, pointed blades, retouched blades, endscrapers (often made on the proximal end of blades; Fig. 5, nos 1–3), and burins (dihedral, on truncation or on break), sometimes made on former Jerzmanowice points, are present. Few truncations, perçoirs, and splintered pieces have been identified in LRJ assemblages. Beedings (Jacobi 2007) also yielded several "Kostenki knives" (Fig. 5, no 3), but their function as a tool is not certain as it is also possible that they were bladelet cores. "Archaic" tool types (sidescrapers, denticulates, notches) are sometimes present but rare, being clearly less common than typologically "Upper Paleolithic" tools.

Concerning blade production technology, some homogeneity is observed between the LRJ assemblages (Flas 2008; Jacobi 2007). The most common knapping method corresponds to blade production using cores with two opposed platforms (bidirectional) (Fig. 5, no 1; examples of blades from bidirectional debitage: Fig. 2, nos 1–3, 5, 7; Fig. 5, no 2), although unidirectional blade production is sometimes also documented. Blade knapping is most of the time done with an organic soft hammer, based on the relative thinness of blade platforms (less than 5 mm, with an average around 3 mm) and the frequent presence of a lip. Blade production is volumetric, involving preparation of the cores by different crests (central crest to initiate blade production and lateral crest to shape the back of the cores and enabling management of the transverse curvature of the knapping surface during the reduction process). The knapping surface is relatively broad with alternating use of the two opposed striking platforms, yielding mostly straight and relatively sturdy blades (around 10 cm and more, in length, ca. 3 cm in width and 1 cm in thickness), sometimes pointed (Fig. 5, no 2). These blade blanks are perfectly suitable to be transformed into Jerzmanowice points.

Bladelet production is likely if we consider some of the cores from Beedings (Jacobi 2007). Indeed, the assemblage includes small bidirectional cores that yielded bladelet-size blanks in the final production stage (Fig. 5, no 4). There are also "core-burin" and "Kostenki knives"

Northern Europe: Middle to Upper Paleolithic Transition, Fig. 4 LRJ. 1: burin on truncation/endscraper, Beedings; 2: endscraper, Goyet; 3: endscraper, Beedings; 4: double burin (on truncation/dihedral on angle), Beedings; 5: double burin on truncation, Robin Hood Cave. 1, 3 and 4: after Jacobi 2007

showing bladelet removals (Fig. 5, no 3). However, because of imprecision during excavation at this site, no complete description of this potential bladelet production can be drawn.

On the other hand, no flake production method has been recognized in the LRJ. The few flakes found in some of the assemblages may simply correspond to by-products of blade

N

Northern Europe: Middle to Upper Paleolithic Transition, Fig. 5 LRJ, Beedings (after Jacobi 2007). 1: Blade core with two opposed platforms; 2: blade; 3: "Kostenki knife"; 4: Bladelet core with two opposed platforms

production or to flakes knapped from exhausted blade cores.

Bone Artifacts and Pendant?

Only two artifacts may possibly indicate the presence of bone tools and ornaments in the LRJ. These are a bone point (or awl) and a perforated ivory disc fragment, both from Ranis 2 (Hülle 1977). Unfortunately these two pieces are lost; the perforated disc being only known from a sketch in a field notebook, as its fragility did not permit it to be removed from the sediment. Given the excavation imprecision at Ranis, one should be particularly cautious about the attribution of these two pieces to the LRJ as no other LRJ assemblage has yielded similar artifacts. Indeed, the bone points described at Nietoperzowa Cave (Allsworth-Jones 1986: 136–137) and Soldier's Hole cannot be accepted, their anthropic nature not demonstrated and their stratigraphic origin uncertain.

The LRJ: An Independent Technocomplex

LRJ Versus Aurignacian

Some researchers have proposed that some LRJ assemblages can be considered as part of the Northern Europe Aurignacian. Yet several arguments converge to confirm that the two complexes are unrelated (Flas 2008).

The stratigraphic associations between diagnostic Aurignacian artifacts and Jerzmanowice points are rare (seven sites). Moreover, they all correspond to unreliable contexts where different industries were mixed because of geological (colluvium) and taphonomic (notably bioturbation) processes and the imprecision of ancient excavations (the seven sites being excavated before 1930). Among recently excavated sites, only Trou Magrite stratum 3 would have yielded an Aurignacian assemblage including a bifacial foliate. However, a preliminary reappraisal of the lithic collection shows that neither the Aurignacian features nor the presence of a bifacial leaf-point can be substantiated and that this assemblage corresponds more likely to a Mousterian industry (Flas 2008: 76).

The current chronological data show that Aurignacian is not found in these Northern European regions before 35,000 BP (uncalibrated; Flas 2008). This implies a hiatus of several millennia with the LRJ assemblages dated around 38,000 BP. The difference between the two complexes is also geographic: contrary to the LRJ, Aurignacian is commonly found in northern continental Europe (Meuse River basin, Middle Rhine basin, southern Poland), but is very rare in Great Britain where it has been found only in a few sites in western England and Wales (Flas 2008; Dinnis 2012).

Moreover, essential differences are obvious in blade production technologies of the two complexes. Indeed, in Aurignacian, blades are produced almost exclusively from unidirectional cores, yielding blanks that are more curved and for the most part lighter (particularly for width and thickness) than in the LRJ (Flas 2008). Blade production technology observed for the Northern Europe Aurignacian is identical to that described for other Aurignacian assemblages in Europe (e.g., Teyssandier 2008).

Central Europe: Jerzmanowician, Szeletian, and Bohunicien

LRJ assemblages from Poland have been sometimes seen as a mere facies of the Szeletian or the Bohunician (Allsworth-Jones 1986; Svoboda 2004: 43); however, the separation of these complexes is still the most likely hypothesis.

Jerzmanowice points are actually very rare in assemblages hypothetically attributed to the Szeletian (one in the assemblage from Mamutowa Cave, Poland) or to the Bohunician (two in the "Bohunician" assemblage from Dzierżysław I lower layer, Poland). Other stratified Szeletian and Bohunician sites did not yield any artifacts similar to Jerzmanowice points. The distinction between the LRJ and the Szeletian is thus not based on the simple proportion of tool types that could be related to the nature of occupations (large settlements with varied activities vs. hunting camps), but has a more profound typological and technological difference (Flas 2008).

Blade production is actually not so well developed in Szeletian assemblages, and blades appear to be mostly knapped from unidirectional cores using hard stone-hammer percussion (Neruda and Nerudová 2005; Flas 2008: 103). This strong difference with LRJ blank production, seen in several sites in different geographic contexts, cannot simply be related to the influence of available lithic raw material. "Krumlovský Les chert," the main raw material of the Moravian Szeletian, does not prevent blade production as it can be seen in the Vedrovice Ia Aurignacian assemblage (Neruda and Nerudová 2005). Moreover, Szeletian assemblages from Southern Poland (Flas 2008), using similar raw material to the LRJ, do not develop a technology similar to the former.

Similarly, the few artifacts described as "Jerzmanowice points" from stratified Bohunician assemblages do not correspond typologically to the LRJ artifacts. Moreover, Bohunician blank production is very specific (Škrdla 2003), producing elongated Levallois-like points, that cannot be mistaken for the blade production seen in the LRJ.

These strong differences between the LRJ, Szeletian and Bohunician are actually confirmed by their geographic ranges: LRJ assemblages are

mainly found in regions (Great Britain, Belgium, Northern Germany) where there are no Szeletian or Bohunician sites.

Discussion. LRJ: An Acculturation Phenomenon of the Last Northern Europe Neanderthals?

There is a consensus among researchers regarding the origins of the LRJ. All agree on the similarities observed between some of the Late Middle Paleolithic industries from Northern and Central Europe (particularly the German *Blattspitzengruppe* or "Altmühlian," or the Belgian "*Evolved Mousterian*") and the LRJ (e.g., Allsworth-Jones 1986; Bar-Yosef 2007; Chmielewski 1961; Kozłowski 1990; Otte 1990). Continuity between these industries and the LRJ is at present perhaps not as obvious than it may seem because of the lack of reliable chronological data and the problems inherent in old collections (Flas 2008); it is nonetheless clear that some technical behaviors seen in the LRJ already existed in industries from the first half of the Interpleniglacial in Northern Europe: the presence of bifacial leaf-points and blade production, especially from bidirectional cores (Piekary IIa and Ksiecia Jozefa sites; Sitlivy et al. 2007).

The LRJ thus developed around 38,000 BP uncal. (or ca. 43,000 BP calibrated) and shows an "Upper Paleolithic" technology and typology, as well as similarities with Late Middle Paleolithic industries of these regions. Then, two questions arise: who are the makers of the LRJ industry (Neanderthals or *Homo sapiens* sapiens)? If they are Neanderthal populations, can the development of an Upper Paleolithic-like industry be explained as the result of an acculturation process stemming from the contact between the anatomically modern humans spreading in Europe around that time?

No human remains are as yet directly associated with the LRJ; hunters responsible for this industry have thus been sometimes considered as Neanderthals by some scholars and as anatomically modern humans by others. For example, Stephanie Swainston (1999: 41) proposed that the LRJ corresponds to "*the earliest intrusive modern human industry*" in Great Britain. It is likely the "evolved" nature of the LRJ blade production and tool types that led it to be so attributed to anatomically modern humans. However, most of the scholars propose that they were Neanderthals because of the technical continuity detected between the LRJ and some of the Late Middle Paleolithic industries (e.g., Bar-Yosef 2007; Otte 1990).

Although no human remains are directly found in association with an LRJ assemblage, it is still possible to consider the available data to evaluate which hypothesis is more likely. Two sites have yielded remains "close" to the LRJ: a maxilla fragment from Kent's Cavern and the three Neanderthal individuals from Spy Cave.

The human remains found in the *Vestibule* of Kent's Cavern raise several issues (Jacobi 2007; Flas 2008; White and Pettitt 2012). Recent studies suggest that previous dating of this bone (around 30,900 BP uncal.) could be a minimum age due to contamination. Some fauna remains found during the same excavations have been dated using ultrafiltration and suggest an earlier age for the maxilla (before 37,000 BP radiocarbon, Higham et al. 2011). However, these human remain come from an unreliable sedimentary context excavated with very unprecise method (Jacobi 2007: 307; White and Pettitt 2012) preventing us from using dates from fauna as indications of its age, and it is only "associated" with nondiagnostic artifacts (blade fragments). Moreover, refitting of these blade fragments indicates an important disturbing of the deposits (White and Pettitt 2012). Recently new datings on more fauna remains (Proctor et al. 2017), notably fauna teeth dated at 32,200 and 32,800 uncal. BP found deeper than the maxilla, confirm the mixing, and do not support the early age previously proposed for the human maxilla fragment. It is thus clearly impossible to use this human remain to relate the LRJ assemblage from this site to an anatomical type nor to suppose an early presence of anatomically modern humans in Great-Britain.

More interesting are the Neanderthal remains from Spy Cave that have been generally related to the Middle Paleolithic assemblage from the upper part of the lower (third) layer, a Mousterian of "Charentian type." However, it should first be emphasized that according to the excavation report, human remains were found directly below the red deposits corresponding to the

second layer, this latter layer including Mousterian, but also LRJ and Aurignacian assemblages. It is thus not impossible, if the bodies were buried, that graves were dug into the lower layer and that these individuals are actually related to occupations in the second layer, thus corresponding to particularly recent Neanderthals.

This late age has been recently confirmed by ^{14}C dates on several bones and teeth belonging to these Neanderthal individuals (Semal et al. 2009). Reliable results for the adult individuals are around 36,000 BP uncalibrated. These dates fit more with the chronology of the LRJ (beginning, as we have seen, around 38,000 BP uncalibrated) than with the final Mousterian chronology that is not found so late in Northern Europe (Pirson et al. 2012). Thus, even if no direct archaeological association between the Spy Cave Neanderthals remains and the LRJ assemblage from that site can be established, these Neanderthals are chronologically more likely related to the LRJ than to the Mousterian.

Despite the lack of direct association of human remains and LRJ, the Neanderthal hypothesis is thus much more likely than the anatomically modern humans hypothesis for several reasons. First, the Late Middle Paleolithic in Northern Europe, from which the LRJ complex seems to have developed, is made exclusively by Neanderthals as is shown by the human remains from Trou de l'Abîme at Couvin (layer dated around 45,000 BP uncal.; Toussaint et al. 2010), Trou Walou layer CI-8 (around 40–38,000 BP uncal.; Pirson et al. 2012), Goyet – *Troisième Caverne* (around 40,000 BP uncal., Rougier et al. 2016) and Neandertal (around 40–39,000 BP uncal.; Schmitz et al. 2002). Second, the dates of the Spy Cave Neanderthals seem too recent to be associated with the Mousterian and fall within the LRJ chronology. They are similar to the dates from the Neandertal remains from Arcy-sur-Cure Grotte du Renne layer X that are attributed to the Châtelperronian (Welker et al. 2016). Moreover, the oldest European anatomically modern humans (Pestera cu Oase: Rougier et al. 2007) are more recent and geographically distant of the LRJ complex.

Explaining why and how important technical and behavioral transformations appeared among Paleolithic societies is a challenging task given the fragmentary and coarse resolution of the available data. In this framework, the acculturation theory, proposing that the European transitional industries (as the LRJ) are the result of acculturation of Neanderthal populations trying to imitate new technical behaviors brought to Europe as the Aurignacian complex made by anatomically modern humans (e.g., Mellars 1989; Bar-Yosef 2007), has the advantage of simplicity. However, several elements suggest that, at least in the case of the LRJ, this hypothesis is rather unlikely. First for chronological reasons: at least 3,000 radiocarbon years separate the oldest dated LRJ assemblage (around 38,000 BP) from the oldest Aurignacian assemblages in the same regions (around 35,000 BP, Flas 2015). While Protoaurignacian assemblages older than 37,000 BP exist in Europe, as at Kozarnika layer VII (Bulgaria, Tsanova 2008) or the lower layers of Isturitz (Southwest France, Szmidt et al. 2010), they remain rare (most Protoaurignacian and Early Aurignacian assemblages postdate 37–36,000 BP). Given the resolution of ^{14}C dates, we do not know if these assemblages are older or younger than, or contemporary with, the LRJ. Certainly these assemblages are distant from the regions where the LRJ developed, and the process by which the presence of blade and bladelet knappers in Bulgaria or the Pyrenees around 38,000 uncal. BP could be the stimulus, across Interpleniglacial Europe, of the development of a blade technology in Northern England and is difficult to imagine. Moreover, as has been previously shown, LRJ blade production strongly differs from the Aurignacian, and it is thus difficult to see how the latter could have participated in the development of LRJ technology, all the more since blade technology is already recognized during the Late Middle Paleolithic of Northern Europe (Sitlivy et al. 2007).

Recently, maybe because an acculturation process related to the Aurignacian complex has been challenged on the basis of chronological and stratigraphic data (e.g., Bordes 2003; d'Errico et al. 1998), other industries have been proposed as proxies for the spread of anatomically modern humans and as acculturators driving the last Neanderthals to develop the "transitional industries" (e.g., Bar-Yosef 2007). In Central Europe, the Bohunician has been seen as a complex related

to the spread of anatomically modern humans from the Near East (e.g., Bar-Yosef and Svoboda 2003). Indeed, it shows similarities with the Boker-Tachtit layers 1–2 assemblages (Skrdla 2003), and Tostevin (2007) has set out in a detailed way how the Szeletian assemblage from Vedrovice V may be seen as the result of acculturation of the local Middle Paleolithic (*Keilmessergruppe* from Kulna Cave) by the Bohunician complex. However, the extension of this model to include a scenario whereby LRJ Neanderthals are acculturated by Bohunician anatomically modern humans finds little support in evidence and is thus a weak hypothesis. There are no human remains showing that the Bohunician complex is made by anatomically modern humans, and it could alternatively correspond to the diffusion of technical ideas rather than to a population dispersal. Moreover, the relationship between Boker Tachtit (in the Negev) and the Bohunician (in Moravia) is based on technological similarities, but intermediary assemblages between these two distant regions are rare (Bar-Yosef and Svoboda 2003) and sometimes show variability (Temnata and Bacho Kiro: Tsanova 2008; Teyssandier 2008). It would be also necessary to assess other European late Middle Paleolithic industries that could potentially play a role in the emergence of the Bohunician, such as the Polish sites of Piekary IIa and Ksiecia Jozefa (Sitlivy et al. 2007), as well as Korolevo I/IIb (Ukrainia; Monigal et al. 2006) and the Bulgarian Moustero-Levalloisian with leaf-points of Samuilitsa and Muselievo (Tsanova 2008). Even if the hypothesis that Bohunician corresponds to an anatomically modern humans dispersal from the Near East is accepted, the LRJ shows different objectives and reduction strategies from the Bohunician. More generally, it is difficult to see which lithic innovations are found in Bacho Kirian or Bohunician industries that could be the stimulus for a long-distance acculturation.

Conclusion

The presence of the LRJ in North-Western Europe confirms the proliferation of technocomplexes during the Middle to Upper Paleolithic transition. In this respect, grouping together different industries under too large and poorly defined labels (such as "Szeletian") masks an essential part of these phenomena.

From an unknown origin, most likely in the context of the *Blattspitzengruppe*, the LRJ complex spread in different milieus at the end of the Middle Paleolithic, between Poland and Wales, regions where bifacial pieces and blade production have been found variably but regularly and which are thus a favorable substrate for the adoption of LRJ technology, a new mixture of already existing behaviors. Once the shift to Jerzmanowice points was established, perhaps related to a change of cynegetic behaviors, and thus the correlative production of suitable laminar blanks, "Mousterian" industries began to change to an "Upper Paleolithic" technology.

Given the available paleoanthropological and chronological data, the LRJ was much more likely made by Neanderthals, whereas the anatomically modern humans expansion in Europe seems to be concomitant with the appearance of the Aurignacian complex. At any rate, the development of the LRJ complex cannot be explained by acculturation from the Aurignacian, this complex being much later in Northern Europe and contributing nothing, at least for blade production, to the technology used by the last Neanderthals.

This shift from Mousterian technology to the LRJ is a further example of the absence of a link between an "Upper Paleolithic" lithic industry and the dispersal of anatomically modern humans, giving credence to the idea of a separation between the cultural and the biological issues involved in the "Middle to Upper Paleolithic transition" (e.g., Hovers 2006). Moreover, it confirms the existence of processes of change within the Interpleniglacial technocomplexes prior to the (Proto)-Aurignacian, as has been described in other European regions (e.g., Teyssandier 2008).

Numismatics, Ancient Greek

Evangeline Markou
Department of Greek and Roman Antiquity (KERA), Institute of Historical Research (IHR), National Hellenic Research Foundation (NHRF), Athens, Greece

Introduction

Ancient Greek numismatics is the study of the coinage produced by the Greek cities, by their colonies in the East and the West – from India to the western Mediterranean – and by many kings, during the Archaic, Classical, and Hellenistic periods. The coinage is described as "Greek" because of the Greek legends on the coins giving a variety of information (e.g., the name of the issuing authority, a die engraver, or a mint official). Ancient Greek and Hellenistic coinage is dated roughly from the end of the sixth century BCE – from the issuing of the very first coins – down to the year 31 BCE, the date of the conquest of Egypt by Octavian. From the year 30 BCE onwards, the Roman period begins.

Definition

The coinage produced by the Greek cities and kings is a material evidence in the service of history. Coins differ from other artifacts in that state authorities issued them; they therefore constitute official documents that were used either by the city or the king who issued them to finance specific needs and to diffuse the messages depicted on their limited surface. The designs and the inscriptions played a monetary as well as a political role (the latter is especially true for the Hellenistic period) and provide precious information about many aspects of Greek civilization. In contrast with modern numismatics, where the metric system is clear and the coins indicate their numerical value, we do not possess a metrological manual for ancient Greek coinage. The numismatist has to find the answers to questions relating to attribution, dating, denomination, value, volume of issue, metal composition, and circulation – amongst others – for each coinage that was produced and survived to the present day. For these purposes, the numismatist must combine the evidence of the coins themselves with other available sources such as ancient texts, inscriptions, and archaeological finds. He will then have to consider the iconography represented on the surface of each coin, the coin legends, the symbols, any monograms, countermarks, or overstrikes – which would indicate the reuse, the "second life" of a specific coin – and employ statistical, metrological, and metallurgical analysis to carry out his research.

The Making of an Ancient Greek Coin

Coin manufacture in ancient times differed completely from modern, automated processes. All ancient coins were produced by hand in the mints of the various cities, which explains their imperfections in terms of shape. In all cases, the procedure was the same (Fig. 1): the first task was to create the blanks or flans of metal of the correct weight (according to the denomination that the mint wanted to issue). Then, the flans had to receive the impression of the obverse and the reverse types, which were engraved in negative (*in intaglio*) on the bronze or iron dies.

The obverse die was fixed in an anvil, while the reverse die was fixed on a punch that was hand-held. The weighed flan was placed on the anvil, and the punch was hit with a hammer, resulting in the impression of both dies on the flan. The result of this process was the transformation of a flan into a coin, a piece of weighed metal bearing the marks of the issuing authority that attested both its validity and its value.

Numismatics, Ancient Greek, Fig. 1 The method of coining in ancient Greece. (From Rutter 1983: 14, Fig. 2, with permission)

The Earliest Coins and the Diffusion of the Coinage

Coinage was first issued probably in Lydia, from where it spread rapidly in the sixth century BCE to mainland Greece (Athens, Aegina (Fig. 2), Corinth), Italy and Sicily, and to specific areas under Persian control during the Archaic and Classical periods (western Asia Minor, Cyprus, Cyrene).

Phoenicians adopted coinage in the middle of the fifth century, and the Carthaginians and the Etruscans later followed suit. The spread of coinage is associated with the development of the city-state (*polis*), but not all cities issued coins. Although electrum (a natural alloy of gold and silver) was used for the earliest coins, the kings of Lydia or the kings of Persia started issuing coins in pure silver and pure gold (bimetallism) around the middle of the sixth century BCE. The Persians continued to produce gold (*darics*) and silver (*sigloi*) coins (Fig. 3) until the time of Alexander III (Alexander the Great), while the majority of the Greek cities issued coins almost exclusively in silver.

Until gold coinage was issued in large quantities by Philip II of Macedonia, by Lampsacus and Cyzicus, by Pixodarus of Karia, and by some kings of Cyprus, the Greek cities mainly issued gold coins in times of crisis. A good example is the coinage minted by the city of Athens at the end of the Peloponnesian War (431–404 BCE) when

Numismatics, Ancient Greek, Fig. 2 Aegina, silver *didrachm* (ca 510 BCE), The Ashmolean Museum, Heberden Coin Room Collection, Oxford. (From Howgego 1997: Fig. 16, with permission)

Numismatics, Ancient Greek, Fig. 3 Persia, gold *daric* (ca 400–330 BCE), The Ashmolean Museum, Heberden Coin Room Collection, Oxford. (From Howgego 1997: Fig. 30, with permission)

Numismatics, Ancient Greek, Fig. 4 Macedonia, Alexander III, silver *tetradrachm* (ca 336 BCE), The Ashmolean Museum, Heberden Coin Room Collection, Oxford. (From Howgego 1997: Fig. 42, with permission)

the Spartans took control of Dekeleia and prevented Athenian access to the mines of Laurion, their principal source for silver (406 BCE). In order to continue financing the war, as Pericles suggested (Thucydides, II, 13.4–5), the Athenians melted down the gold plates of seven statues of Victory and produced a gold coinage composed of various denominations (from *staters* down to *hemiobols*) that survive in a few examples today. In parallel, the Athenians issued a series of silver-plated coins (silver on the exterior and bronze in the interior), mentioned as "πονηρά χαλκία" in Aristophanes (Frogs, 717–733). Each of these coinages represents a solution of making payments and facing financial difficulties during a period of crisis.

From the middle of the fifth century BCE, some Greek cities also minted coins in bronze, a coinage of a small value that was designed to cover mostly everyday needs, which explains its local diffusion. Hoard evidence, as well as other finds, proves that fractional coinage was issued in important quantities during the Classical period by many cities.

The rise of the kingdom of Macedonia, with Philip II (360–336 BCE), who exploited the gold mines in the territory of Krenides to pay for mercenaries, then with Alexander III (336–323 BCE) and his campaign that led to the fall of the Persian Empire and the conquest of the East, changed the political scene of the Greek world and inaugurated a royal coinage of a broader scope (Fig. 4).

Alexander III gained control of the Persian treasury c. 333–330 BCE and accessed a massive amount of silver (both coined and in other forms); this booty, calculated at 180,000 *talents* of silver (a Greek *talent* is roughly equivalent to 26 kg), financed his campaign. With Alexander's conquests, coinage in gold, silver, and bronze was issued in the east, at Babylon, at Susa, and at Ecbatana, the former principal cities of Persia, while around 200 BCE, Greek coinage was produced in western India. It was even adopted by the Parthians and the Sassanians. In the north, the coinage of Phillip II and Alexander III was imitated by the Celts, the cities in the Danubian region, and later on in Gaul and Britain.

After the death of Alexander III, his empire was divided amongst his Generals. Although coinage in the name and with the types of Alexander continued to be issued after his death by these successors (the Diadochoi) for reasons of legitimization of the dynasties, soon after the adoption of the title of *βασιλεύς* – king – in 306, they started issuing coinage with their own types and legends. In the Seleucid dynasty, it is Antiochus I (281–201 BCE) who first placed his own portrait on the coins (Fig. 5), but the *Alexanders* were a dominant currency in the Seleucid Empire that retained the Achaemenid system of the division of the satrapies but – contrary to the Persian policy – did not normally allow the satraps to mint their own coins.

In the Ptolemaic kingdom, the royal Ptolemaic coinage was imposed around 290 BCE, and there is evidence for the exclusive use of the Ptolemaic currency in the kingdom which also applied in the areas of Ptolemaic control such as Cyprus, Phoenicia, and

Numismatics, Ancient Greek, Fig. 5 Antiochus I, Mint of Seleuceia on the Tigris, silver *tetradrachm* (ca 274–270 BCE), The Ashmolean Museum, Heberden Coin Room Collection, Oxford. (From Howgego 1997: Fig. 70, with permission)

Palestine. The Ptolemaic "closed currency system" created revenue, because foreign coins that were heavier in weight were exchanged for local coins that were lighter in weight and were legal tender in Egypt and in the areas of Ptolemaic control (at the beginning of the third century BCE, the Athenian tetradrachm weighed 17.2 g while the Ptolemaic one weighted 14.3 g). This type of exchange also helped to retain silver in Egypt, which did not possess any natural sources of that metal.

The Attalid dynasty at Pergamum, founded by Philetaerus, became a major force in Asia Minor in the third and second centuries BCE. The coinage produced adopted Alexander types in the name of Alexander, then of Seleucus, then the portrait of Seleucus with the name of Philetaerus, and his successors adopted the head of Philetaerus on their coinage.

At the beginning of the second century BCE, the introduction of the cistophoric coinage reflects a major change. The name of this coinage derives from the representation of a sacred chest (*cista*) on the coins, and in contrast to other royal coinages, it does not bear a portrait and is signed by the cities that produced it. The cistophoric coinage was issued by a number of cities and was used exclusively in the Attalid territory; it was lighter than the Attic weight by approximately 25%. Although this practice brings to mind the Ptolemaic system, the Attalid one is more complicated since the Attic weight standard was still used for export.

In the Hellenistic period, the royal coinages circulated together with the coinages of the Leagues – that is, the confederations of cities such as the Arcadian and the Boeotian – as well as those of specific cities with a status a part, such as Rhodes and Carthage.

Weight Standards

The coin, νόμισμα, is a piece of metal whose official stamp guarantees its weight and value. Each weight belongs to a specific weight standard that was adopted by the different cities (Table 1). Studies carried out in the nineteenth century have identified the main weight standards (Attic, Aeginetan, Thraco-Macedonian, Persian, as well as various local standards) that were adopted by many peripheral cities. It is still very difficult to completely understand these standards and fully trace the fractions – subdivisions of the main unit – their theoretical weight, or their exchange ratio to other coinages and/or other metals.

The best-known example is that of Athens, where the *drachm* is the basic unit: 100 *drachms* made up one *mina* and 6.000 *drachms* – that is, 60 *minae* – made up one *talent*. The *mina* and the *talent* of course describe the weight or the value of silver and do not refer to coins. The standard coin on the Attic weight standard was the *drachm* (ca 4.36 g), and there were multiples (in Athens the *decadrachm* is the highest denomination) and fractions down to 1/48 of a *drachm*, whose names appear in the texts, and are based on the equivalence of 1 Attic *drachm* to 6 *oboloi* of ca 0.72 g.

In many cases, die studies of individual coinages and thorough metrological analysis have permitted an approach to the assessment of the theoretic weight of specific weight standards.

Coin Circulation

The combined evidence of isolated coin finds and of coin hoards of different types (whether emergency or by accumulation) that were never recovered by their owners for various reasons is very important for the dating of the coins included in the hoard and for understanding the area in which specific coin types and denominations circulated. The *Inventory of Greek Coin Hoards* (IGCH) is the first publication that combined the known

Numismatics, Ancient Greek, Table 1 Some weight standards of the ancient world

Weight standards of the Greek World					
Attic			Aeginetan	Corinthian	Samian
Denomination	Number of Drachms	Grams	Grams	Grams	Grams
1 Decadrachm	10 drachms	43.66			
1 Tetradrachm	4 drachms	17.44			17.40 (stater)
1 Didrachm	2 drachms	8.72	12.6 (stater or didrachm)	8.6 (stater)	8.70 (1/2 stater)
1 Drachm	**drachm**	**4.36**	**6.3**		
Pentobolon	5/6	3.63			
Tetrobolon	2/3	2.90			2.90 (1/6 stater)
Triobolon	½	2.18	3.15		
Diobolon	1/3	1.45			1.45 (1/12 stater)
Trihemiobolion	¼	1.09			
Obol	**1/6**	**0.72**	**1.05**		**0.73 (1/24 stater)**
Tritartemorion	1/8	0.54

Tetartemorion	1/24	0.18			
Hemitetartemorion	1/48	0.09			

N

hoards up to 1973, and since then, nine volumes of *Coin Hoards* (CH), supplementing the initial catalogue, have been published (Thompson et al. 1973).

Metal Composition

The evolution of research during the twentieth century has permitted nondestructive analysis to be carried out on coins, in the search for metallic composition. Today, there are various methods that study only the surface (X-ray fluorescence (XRF and EDXRF)), a small ablated portion of the coin in the nanogram range (LA-ICP-MS), or a more important area of the object (nuclear techniques using cyclotrons such as neutron activation analysis (12 or 14 MeV)). In-depth techniques look for trace elements that could indicate the provenance of the metal and maybe that of the mint, together with the major elements such as gold, silver, and bronze. The purity – or not – of the metal can help the researcher to detect any intentional manipulations of the coinage's alloy by the issuing authorities that could help them economize in precious metal and help their cities in times of crisis.

Coin Types

Greece was not a unified state; the traditions, customs and origins of individual cities were reflected in the great variety of surviving iconographical types and coin legends.

The coins of the Archaic period mostly bear images of animals and plants, often because they are related to the products of the city or to its name. At Ephesus, the bee represented on the coins is related to the cult of Artemis, whose priests were known as "bees"; on coins of the island of Melos, the apple (μήλο in Greek) is represented, while at Selinous in Sicily, the leaf of a wild celery (σέλινον in Greek) refers both to the local products of the area and to the city's name (a "canting" or "punning" type).

Numismatics, Ancient Greek, Fig. 6 Athens, silver *tetradrachm* (ca 450 BCE), The Ashmolean Museum, Heberden Coin Room Collection, Oxford. (From Howgego 1997: Fig. 21, with permission)

Numismatics, Ancient Greek, Fig. 7 Bactria, Demetrius I, silver *tetradrachm* (ca 200–190 BCE), The Ashmolean Museum, Heberden Coin Room Collection, Oxford. (From Howgego 1997: Fig. 75, with permission)

Some cities represent images associated with local myths and traditions on their coins. In Athens (Fig. 6), from the end of the sixth century BCE, the type of Athena, the patron deity of the city, on the obverse and her sacred bird, the owl, on the reverse, with the coin legend AΘH became the characteristic types of Athenian coinage for five centuries.

During the second century BCE, the *stephanephoroi* coinage, known as "new style coinage," is named from the wreath within which the reverse design appears. Likewise, the coins of Corinth and those of Corinth's colonies represent in the fifth century BCE Athena on the reverse and on the obverse the mythical winged horse Pegasus who was tamed by the Corinthian hero Bellerophon, images that are both linked to the local myth. A sandal on a coin of Larissa alludes to a local myth about Jason, while the shield on the Boeotian coinage can be linked to the various labors of Heracles, represented on the obverse of those coins.

On rare occasions, the coin types bear a clear political symbolism, such as the control of one city by another. This is the case of the coins with Samian types issued by the Samians who occupied Zancle in Sicily in the years 493–488 BCE. Similarly when Theron, the tyrant of Acragas, conquered Himera in Sicily around 483 BCE, he altered the weight standard and depicted a crab, the characteristic type of his coins, on the reverses of the coins of the occupied city.

The earliest coins to feature portraits of living rulers first appeared in the fifth and fourth century coinages of Persian satraps of Asia Minor, such as Pharnabazos on the issues of Kyzikos, Perikles on the *tetradrachms* of Lycia, and Tissaphernes on the *tetradrachms* of Lydia. Individualized and lifelike portraits on coins (Fig. 7) became a characteristic feature of the Hellenistic period: the portrait was the main type on the obverse of the coinages of the Hellenistic rulers and was linked to the legitimization of the monarchies and the divinization of the rulers through their representation with divine attributes.

Coin Legends

Archaic, Classical, and Hellenistic coinages bear a great number of inscriptions in various local scripts. The most common inscription of the early coinages is that of the name of the city and more specifically that of the citizens. It is either represented in full (on the coins of Syracuse ΣYPAKOΣIΩN –of the Syracusans–) or in abbreviated form (as in the case of the Athenian coinage where the reverse legend AΘH abbreviates the word AΘHNAIΩN –of the Athenians–) or even as a single letter (the Archaic Greek letter *koppa* is the initial of the Corinthians on the coinage of that city) (Fig. 8).

The colonies of Corinth, although they bear the same iconography as their metropolis, differentiate their issues through the initials of their cities, Greek letters that appear below the winged horse on the reverse: for example, the letter *Λ* on the coins of Leucas and the letter *E* on those of Epidamnos. In areas such as Cyprus, Phoenicia, or Lycia, other local scripts were used on the coinages, indicating the issuing authority.

Numismatics, Ancient Greek, Fig. 8 Corinth, silver *tridrachm* (ca 345 BCE), The Ashmolean Museum, Heberden Coin Room Collection, Oxford. (From Howgego 1997: Fig. 18, with permission)

Alexander III placed his name and royal title on his coins, and rulers in the Hellenistic period used the Greek alphabet to indicate the name of Alexander, the name of the founder of the dynasty or their own name, followed by the title *ΒΑΣΙΛΕΩΣ* (of the king).

In addition to the coin legends, punch marks, regal dates, monograms, and magistrates' names offer additional information on the coinage of the cities and kings during the Archaic, Classical, and Hellenistic periods.

Historical Background

The collecting of Greek and Roman coins goes back to ancient and medieval times, but the study of these coinages dates from the Renaissance period in Italy, where collections were formed in the aristocratic houses (Médici, Gonzaga, Este). The work of Andrea Fulvio, *Illustrium Imagines*, dates from the sixteenth century (1517), while the very first numismatic book, *De asse et partibus ejus*, was published around that same period by Guillaume Budé (1514). In the next centuries, studies accumulated, and the eighteenth century is marked by the synthetic works of J.C. Rasche, *Lexicon universae rei numariae* (Leipzig, 1785–1805), and J.H. Eckhel, *Doctrina numorum veterum* (Vienna, 1792–1798). The establishment of the chronological perspective of Greco-Roman art, the archaeological discoveries of the nineteenth century, and the use of photography made a more substantial volume of numismatic material available for study. From the nineteenth century also begins the publication of the major coin collections in Paris (*Traité des monnaies grecques et romaines*) and in London (the *Greek Coins in the British Museum*, abbreviated as BMC). In the twentieth century, many studies of individual mints were carried out, reconstructing not only the numismatic production according to the various periods but also the analysis of the monetary politics of the issuing authority. This type of numismatic research is in our era enhanced by coin die studies, metallurgical analyses of the coins, and the application of statistical methods in numismatics that help calculate the volume of the coinages produced in a specific period.

Key Issues/Current Debates

The questions of why coinage was invented and what it's original purpose was, still have no precise answer. The issuing of the very first coins still gives rise too many discussions concerning the issuing authority that first came up with the idea of coinage – was it produced by a state or by individuals and what was the function of these coins? Although it was believed that the earliest coins were first struck in the kingdom of Lydia, evidence deriving from ancient written sources (Xenophanes and Pollux 9.83), from coins found in an archaeological context and from the existence of natural sources of electrum in the area (Herod. 1.93; 5.101), permits to argue otherwise.

Likewise, the chronology of the spread of the coinage to the Greek world is also highly uncertain and under discussion because the only datable archaeological context for the sixth century coinage is the Apadana foundation deposit in Persepolis, whose dating is placed at some point in the last quarter of the sixth century. For the fifth century, the coins found in archaeological contexts multiply, and hoard evidence offers a more concrete basis for the dating and the attribution of specific issues.

The complete understanding of the various local or "international" weight standards and especially the denominational value relation to silver, gold, and bronze issues of the various authorities is still in progress. Discussions concern the theoretical weight of denominations and

their exchange ratio as well as the attribution and dating of bronze coinages to the issuing authorities. As C. Kraay stated in 1966, "The attainment of [an] accurate chronological classification is the primary task of Greek numismatics today" (Kraay and Hirmer 1966: 20). In order to provide full and reliable information today, almost 50 years later, that task is still necessary.

International Perspectives

Research in ancient Greek numismatics has much developed in the past years, with the help of international collaborations, research projects, and online databases that make the numismatic material accessible to a much broader audience of numismatists, archaeologists, historians, and other interested members of the public.

The biggest collaborative publication effort of the past decades has been the *Sylloge Nummorum Graecorum* (SNG) project, the publication of illustrated catalogues of Greek coins in public and private collections in the British Isles, Denmark, France, Germany, Greece, Israel, Sweden, Switzerland, Italy, and the United States. The SNG collection is coordinated by the International Numismatic Commission (http://www.muenzgeschichte.ch/inc/index.html), and today it exceeds 120 publications and is accessible online (British Academy research project: http://www.sylloge-nummorum-graecorum.org/). The project *Achémenet* (http://www.achemenet.com/) collects and diffuses various sources related to the Achaemenid Empire, from publications to detailed descriptions of objects and coins. At the same time, the project *Lexicon Iconographicum Numismaticae* (LIN) from the collaboration of the Universities of Messina, Bologna, and Milan aims to put together a method for the iconographical analysis of coin types.

Future Directions

The general bibliographies in numismatics are today a valuable tool to enable the researcher to discover the latest publications. The most important general bibliography of numismatic publications (Clain-Stefanelli 1985) is currently supplemented on a biannual, annual, or even five yearly basis. These numismatic bibliographies can be found in Numismatic Literature (published twice a year by the American Numismatic Society), the "Numismatic" section of *L'Année Philologique* (Paris, Belles Lettres), the "Numismatik" section of the *Archäologische Bibliographie* (published annually with the *Jahrbuch des Deutschen Archäologischen Instituts*), and finally the *Survey of Numismatic Research*, the collection with a brief commentary of the numismatic publications that appear in the 5-year interval between each *International Numismatic Congress* (the most recent one is covering the years 2002–2007, containing over 12,000 publications from ca 4,000 authors, and it was published on the occasion of the XIV International Numismatic Congress in Glasgow that took place in 2008).

The Internet today offers a broader accessibility of coin information. Museums have started to publish their numismatic collections' databases online (The Fitzwilliam Museum in Cambridge: http://www.fitzmuseum.cam.ac.uk/opac/search/searchcm.html/The British Museum in London: http://www.britishmuseum.org/collection/The American Numismatic Society in New York: http://numismatics.org/search//The Cabinet des Médailles de la Bibliothèque Nationale de France in Paris). At the same time, coin auction archives (http://www.coinarchives.com/) today offer high-quality digital images and important information on coins that were sold in coin auctions and now reside in either private or public collections.

Numismatics, Roman Imperial

Nathan T. Elkins
Department of Art, Baylor University, Waco, TX, USA

Introduction

Roman imperial numismatics is the study of coins and medallions of the Roman Empire from the commencement of the reign of Augustus in 27 BCE to the reign of Anastasius (CE 491–518), whose coinage is arbitrarily chosen as the beginning of the Byzantine series on account of his bronze coinage reform. Ancient coins have survived to the modern era either because they were hoarded or randomly lost ages ago.

Definition

Roman imperial numismatics may be viewed as a subfield of ancient history or archaeology or as a specialized discipline in its own right. The educational background of a numismatist largely colors his or her approach to the subject and the sorts of questions that a numismatist will pose. For

instance, historians tend to appreciate coins as a source material for economic or narrative history in concert with textual evidence. Archaeologists have been more interested in coins as chronological indicators for their sites, although coins in context also say much about the movement of populations, localized economic conditions, and coin circulation. Art historians attend to the iconography of Roman coins, consider the semantic meaning of designs, and compare coin designs with artworks or iconographic themes in other media. Traditionally, those who identify themselves as numismatists, and who concentrate on the medium of coinage alone, grapple with the field's specialized methods, such as die studies, hoard analysis, metrology, and so on, all of which reflect more upon production context rather than the context of use or deposition that are of greater concern to archaeologists, art historians, and historians. But today, greater care is taken to apply interdisciplinary methods in the field of numismatics.

For approximately 250 years, Roman imperial coin denominations followed the structure inherited from the Republic that was based on the silver *denarius* (Fig. 1; an Augustan *denarius* is illustrated in Fig. 2). The gold *aureus* was the largest denomination worth 25 *denarii*. The regular production of a subsidiary bronze coinage was an imperial innovation. The largest bronze denomination, the *sestertius*, was introduced by Augustus in 23 BCE. It and the *dupondius* were made of a copper-zinc alloy known as *orichalcum* (brass) that gave the coins a bright, golden

	Aureus (gold)	Denarius (silver)	Sestertius (brass)	Dupondius (brass)	As (copper)	Semis (copper)	Quadrans (copper)
Aureus	1						
Denarius	25	1					
Sestertius	100	4	1				
Dupondius	200	8	2	1			
As	400	16	4	2	1		
Semis	800	32	8	4	2	1	
Quadrans	1600	64	16	8	4	2	1

appearance. This original color is not apparent after centuries of patination. However, *sestertii* and *dupondii* from the anaerobic layers at the Vindolanda excavations in northern England maintain their original appearance on account of the lack of oxygen. Smaller denominations, the *asses* and the irregularly produced *semisses* and *quadrantes*, were struck in copper which gave them a reddish color. Even in antiquity as base metal coins circulated through the years, they darkened and oxidized. This often caused confusion between the *dupondius* and the *as*; although the *dupondius* was heavier, it was approximately the same diameter as an *as*. In Nero's principate (54–68 CE), the bust of the emperor on the obverse of the *dupondius* began to be depicted with a radiate crown (Fig. 3) in order to distinguish it from the *as*, upon which the emperor typically wore a laurel crown.

Nero decreased the weight of precious metal coins and the silver coinage was gradually debased through the reign of Septimius Severus in the third century CE. Caracalla (211–217 CE) introduced a new silver denomination, the *antoninianus*, which featured the emperor's portrait with a radiate crown (Fig. 4) to differentiate it from the *denarius*. The *antoninianus* was meant to circulate as a double *denarius* in spite of the fact that it contained only one and half times the amount of silver than the *denarius*. Elagabalus discontinued production of *antoniniani*, but they were reintroduced by Balbinus and Pupienus and soon became the silver standard for the rest of the third century. By the reign of Gallienus, the silver content of the *antoninianus* had become superficial (Fig. 5 shows an *antoninianus* with a green patination, the result of high copper content). *Sestertii*, *dupondii*, and *asses* were no longer produced as the *antoniniani* had essentially become a bronze coinage.

It is important to note that the Roman imperial coinage is distinct from the Roman provincial coinage, minted by cities for local use. A local coinage was struck by some cities in the Roman West until the principates of Tiberius (14–37 CE) and Caligula (37–41 CE) when the western provincial coinage died out. In the eastern Roman Empire, provincial coinage survived until the

later third century. Roman imperial coinage was the official currency of the Roman Empire, produced at the mints of Rome and Lugdunum (Lyon, France) until Vespasian's reign when the imperial coinage became the prerogative of Rome. Nevertheless, military mints or branches of the imperial mint were in operation at various times in Rome's history and are typically included under the definition of "imperial coinage." As political power shifted away from Rome during the political, military, and economic turmoil of the third century, branch mints became the norm. In fact, the mass production of highly debased *antoniniani* by imperial mints operating in the eastern provinces was probably the reason that local mints closed in the late third century as the debased imperial currency negated the need for a locally produced bronze coinage (Burnett 1987: 63–65).

Under Diocletian and Constantine, a series of imperial mints stretching from London to Alexandria were established. Diocletian also attempted to reform the coinage with a genuine silver coin. There were also numerous attempts in the fourth century to standardize and stabilize the coinage (for a summary of third century and fourth century monetary history and changes in the organization of mints, see Burnett 1987: 63–65, 122–125; Howgego 1995: 136–140; and relevant contributions in Metcalf 2012). Although there were some purer silver coins, billon and copper coins dominated the fourth and fifth centuries CE; in the fifth century, copper *nummi* traded at 7,200 coins to the *solidus*, the standard gold denomination in the fourth and fifth centuries. Fourth and fifth century billon and copper coins were mass-produced and are, therefore, among the most common finds from excavations at Roman imperial sites.

Roman imperial gold and silver coins circulated across the Empire's wide expanse, and even beyond it. Roman gold *aurei* are commonly found in India and testify to the extent of Rome's trade. Roman imperial bronze coins were less mobile. *Sestertii*, *dupondii*, and *asses* are found more commonly in the western Roman Empire where the provincial mints had ceased to operate by the second quarter of the first century; eastern cities relied more on their local coinage. But even imperial bronze coins tended to circulate locally once they had been introduced into a region (on coin mobility and circulation, see, e.g., Duncan-Jones 1989, 1999). The absence of an adequate supply of bronze coins in the Roman West is apparent in various periods and in certain regions. In Germania, for example, local imitations of the imperial coins of Claudius were commonplace as the official coinage was in short supply (compare Figs. 6 and 7). After the establishment of imperial mints across the Empire under Diocletian and Constantine and the

Numismatics, Roman Imperial, Fig. 6 Orichalcum Sestertius of Claudius, Yale University Art Gallery, 2001.87.5471

Numismatics, Roman Imperial, Fig. 7 Imitation of a Sestertius of Claudius. Yale University Art Gallery, Gift of James H. Schwartz, 2005.6.78

implementation of a uniform coinage from Britain to Egypt, imperial bronze coinage was used everywhere but site finds as a rule tend to be comprised of coins from the most proximate imperial mint. The irregularly produced *semisses* and *quadrantes* of the first and second centuries appear to have been struck for special purposes in Rome and Italy and are more common there than in the provinces. Their occasional presence in frontier regions on the Rhine may be connected with the movement of soldiers or the imperial court (e.g., Kemmers 2003. 2006: 218–219).

Historical Background

Modern study of Roman imperial coinage began in the Renaissance (consult generally Clain-Stefanelli 1965; Giard 1981). Coins are among the most common material objects to have survived the ages; their small size and portability made them desirable collectibles for aristocrats and antiquarians who developed a taste for ancient art. Early students of numismatics published aristocratic collections, some of which became the basis of the collections in today's encyclopedic

N

museums. These early numismatic books often failed to present the material in a systematic fashion and were rife with speculation, fantasies, and forgeries. Inspired by the detailed representations on Roman coinage, Renaissance artisans achieved an aesthetic quality in medallic art that had not been witnessed since Roman antiquity. At the same time, the demand for Roman coins led to the production of forgeries and fantasy pieces, a problem that continues to plague numismatics even to this day.

Serious study of numismatics began with Joseph Eckhel whose work was the first attempt to organize the vast corpus of coins in a systematic way and to sort out all the fantasies and forgeries (Eckhel 1792–1798). Antiquarian study of coins provided scholars with a detailed knowledge of coin production, mints, and chronologies, but the intense focus on the object itself limited and isolated the field. The great Roman historian Theodor Mommsen demonstrated the greater role that numismatics could play in the historical sciences with the publication of his seminal numismatic monograph in which he brought numismatics together with the critical application of epigraphic and textual evidence (Mommsen 1860); he was also one of the first scholars to make extensive use of hoard evidence.

Key Issues/Current Debates

The bronze coinage of Augustus regularly bore the reverse legend S(*enatus*) C(*onsulto*), meaning "by decree of the Senate." *S C* remained on the regular imperial bronze coinage until its disappearance in the third century. The abbreviation only rarely appeared on precious metal coins of the Roman Empire, and usually as *EX S C* when it did, in order to call attention to an act of the Senate. Mommsen (1860: 739–750) argued that *S C* indicated that the base metal coinage was the responsibility of the Senate while the lack of it on the gold and silver coinage proved they were the prerogative of the *princeps*. This rigid diarchal interpretation dominated numismatic thought for much of the twentieth century; some scholars even assumed that Rome was home to two mints, one for precious metal ("the imperial mint") and one for bronze ("the senatorial mint"). Now the majority of scholars postulate that *S C* on the bronze signified only the Senate's nominal role as the visible authorizer for the withdrawal of bronze coinage from the treasury, even though the *princeps* had come to hold that power in actuality (e.g., *RIC*^{2} I: 24, 32). No longer does the presence of *S C* on the bronze coinage affect the interpretation of designs on Roman imperial coins since, in essence, visual messages would have originated from the imperial court, not the Senate.

Hoard analysis remains an important tool available to numismatists. Hoards are dated by the latest coin in the group to provide a *terminus ante quem*. Hoards can also be compared with one another to establish chronologies for the coins themselves. The Reka-Devnia hoard is the largest and most famous hoard of Roman imperial silver coins (Mouchmov 1934; Depeyrot 2004). It was so large that it was a primary source for the writing of *Roman Imperial Coinage* (*RIC*), the standard imperial type catalogs, the earliest volumes of which were published in the early twentieth century. Recently, there has been a growing interest in quantifying the reverse types represented in coins hoards in order to examine the evidence that this might yield regarding the semantic value of numismatic images in the Roman world (e.g., Noreña 2001; Depeyrot 2004). Individual coin finds are useful for archaeologists as they can date archaeological strata and features. They can provide additional information on coin circulation and can also indicate pathways and other highly trafficked areas at a site.

Unfortunately, hoards and individual finds are most often unrecorded as coins are one of the most sought-after and collected forms of antiquities. Presently, most of the numismatic material that enters the trade is looted from Eastern European and Middle Eastern countries. Often there are highly organized criminal networks that pay gangs of metal detectorists to find coins, which are then smuggled and sold to European and American dealers. The situation in Bulgaria is particularly grim (e.g., Dietrich 2002; Petkova

2004). Dietrich (2002) records an instance in which a Bulgarian supplier to American dealers spirited a metric ton of ancient coins to the United States in 1999.

International Perspectives

In recent decades, national projects have begun to inventory coin finds within their own political boundaries. The best inventories come from the area of the former northwestern provinces of the Roman Empire, and especially the area of modern Germany. At the time of writing, 41 volumes of *Die Fundmünzen der römischen Zeit in Deutschland* (*FMRD*) have been printed, cataloging a combined total of approximately 300,000 to 350,000 coins. The first volume of *FMRD* was published in 1960, but since then, numerous other countries and regions have initiated similar series: *Die Fundmünzen der römischen Zeit in Österreich(FMRÖ)*,*Die Fundmünzen der römischen Zeit im Größherzogtum Luxemburg (FMRL)*, *Die Fundmünzen der römischen Zeit in Slowenien* (*FMRSl*), *Die Fundmünzen der römischen Zeit in den Niederlanden* (*FMRN*), *Die Fundmünzen der römischen Zeit in Kroatien* (*FMRHr*), *Die Fundmünzen der römischen Zeit in Ungarn(FMRU)*, *Die Fundmünzen der römischen Zeit in Polen* (*FMRP*), *Inventar der Fundmünzen der Schweiz* (*IFS*), and *Ritrovamenti monetali di età romana nel Veneto* (*RMRVe*). Some of the above projects have recently begun placing material online as well. Other regions such as England and Wales have online finds databases, including the Portable Antiquities Scheme (http://finds.org.uk/) which currently has recorded approximately 400,000 finds reported by metal detectorists. A large group of c. 70,000 coin finds from Rome is being prepared for comprehensive publication, but already the custodians of that data have frequently made the unpublished information available to scholars for study. Finds inventories such as these provide the groundwork for contextual numismatic research and questions that can be asked from across a number of historical disciplines (e.g., see entries in von Kaenel and Kemmers 2009).

Future Directions

Today, Roman imperial numismatics lays at the intersection of economic, historical, art historical, and archaeological research. Nonetheless, many scholars fail to consider numismatics, do not deploy its full potential, or use coins recklessly in their research. The fear of numismatics is perhaps due in part to the fact that numismatic methodology can be highly specialized and that a very narrow object-based avenue of inquiry continues to exist (discussion in von Kaenel 1994). While studies based on the objects or production contexts alone unquestionably have their applications and merits, they can be irrelevant or even unintelligible to historians outside of the small circle of numismatic specialists. Numismatists have had some difficulty making their work accessible and relevant to those who write history. It is a worthwhile challenge then for a scholar to have a command of the historical sources and material or visual culture and also to develop a deep and thorough knowledge of numismatic resources and methods. Interdisciplinary approaches are a necessity for numismatists working in the twenty-first century.

The Roman imperial coinage has been thoroughly cataloged and published, and thus there is ample room for the methodical application of numismatic evidence, especially in visual and archaeological studies. Excavated coin finds have always been of importance to archaeology for their potential to provide essential chronologies for sites and their accompanying strata (Casey and Reece 1988 is a commonly cited introduction). Over the past few decades, critical methods to deal with coin finds have been greatly advanced, particularly by the Frankfurt School (see, for example, methodological discussions in R.-Alföldi 1979; von Kaenel and Kemmers 2009). But in addition to their utility as chronological indicators, attention to archaeologically recovered finds can provide information on economic conditions, coin supply and circulation, military activity, and beyond. Coin finds can give insight into ritual practices and other forms of human behavior, as at Avenches where excavations determined that the living preferred to

deposit imperial coins with specific reverse types such as Pax, Salus, Felicitas, and Roma with the deceased (Koenig 1999).

Since the 1980s, it had been understood that the Roman state intermittently supplied the western provinces with bronze coinage. Recent research has additionally suggested that the Roman state chose to supply different populations with bronze coins laden with appropriate reverse iconography in order to communicate ideas to those populations. This phenomenon is best illustrated at Nijmegen where the Flavian bronze coin finds from the legionary fortress show a much stronger proportion of martially themed reverse types than the finds from neighboring civilian settlements or from Rome (Kemmers 2006: 189–244). This discovery ought to set an agenda for scholars asking questions about the communicative value of Roman imperial coins (Elkins 2009).

Numismatics, Roman Republican

Eleanor Ghey
Department of Coins and Medals, British Museum, London, UK

Introduction and Definition

The study of the coinage of the Roman Republic covers the period from the introduction of coinage in Rome in about 300 BCE to the end of the Roman Republic. In numismatics, the latter is conventionally dated to 31 BCE, the date of the battle of Actium and the establishment of the new political order, the Roman Empire. Traditionally, the discipline only encompasses coins issued under the direct authority of Rome and excludes related contemporary coinage issued in Italy and the Mediterranean region.

Historical Background

The Development of Roman Coinage

Before the rise of the Roman Republic, some areas of Italy had developed a tradition of coinage on the Greek model from the sixth century BCE. This was however not adopted in the area of Rome, where the earliest money appears to have been in the form of bullion and currency bars.

Around the fourth century BCE (the date is not certain), cast bronze currency bars appeared, based on the weight standard of the Roman pound (about 324 g). From about 300 BCE, this was joined by the production of struck bronze and silver coins. By the early to mid-third century BCE, there were three separate monetary systems operating in Rome:

1. Cast rectangular bronze currency bars, sometimes referred to as "*aes signatum*."
2. Cast circular bronze coinage, otherwise known as "*aes grave*."
3. Struck coinage (silver and bronze) based on the Greek model but for the first time inscribed in the name of the Roman people. The silver and bronze coinage was derived from the coinage of southern Italy and appears to have had a more southerly geographical distribution than the cast coinage.

The currency bars appear to have been a fairly short-lived phase and went out of use in the middle of the third century. Around this time, the other elements were combined and operated as a single monetary system of gold and silver coins and cast bronze. A standardized design was adopted for this coinage, with a janiform head on the obverse of the silver "*quadrigati*" (so-called by numismatists for their reverse design featuring a *quadriga*, or four-horse chariot) and the cast bronze coins.

The denominations of the bronze coinage were based on divisions of the *as* (originally one Roman pound (the libral weight standard) but gradually devalued so that this became a token coinage). One *as* was divided into 12 *unciae*; the number of these represented by each coin was shown in the denominational markings on bronze coins, as in Table 1 below. These denominations remained throughout the Roman Republican period, although the weight standard of the bronze coinage suffered successive reductions over time and there were periods when bronze coinage was not issued.

Reforms of the Second Punic War

The function of coinage in the third century BCE seems to have been primarily as a tool for the state to make some payments for military and civic purposes. The very difficult military period of the second Punic War (218–201 BCE) saw successive reforms of the coinage in the form of devaluations and weight reductions (from libral, to semilibral, and post-semilibral bronze coinages) and a short-lived series of high value gold denominations. This probably reflects the unprecedented demands made on the Roman treasury at that time.

This turbulent period in Rome's monetary history ended around 211 BCE with the introduction of a completely new currency system based on the *denarius* (ten asses). This denomination persisted into the third century CE. The *denarius* was a

Numismatics, Roman Republican, Table 1 Denominations of the *denarius* system

Denomination	Date in use	Mark	Metal	Multiple of an as
Aureus	Intermittent		Gold	400 (25 *denarii*)
Denarius	c. 211 BCE	X	Silver	10
Denarius (revalued)	From 141 BCE	XVI, X crossed or X	Silver	16
Quinarius	Intermittent	V	Silver	5
Sestertius	Intermittent	IIS	Silver	2 1/2
"Victoriatus"	Up to c. 170 BCE		Silver (base)	
As	c. 215 BCE to 80 BCE	I	Copper alloy	1
Semis	c. 215 BCE to 80 BCE	S	Copper alloy	1/2
Triens	c. 215 BCE to 80 BCE	••••	Copper alloy	1/3
Quadrans	c. 215 BCE to 80 BCE	•••	Copper alloy	1/4
Sextans	c. 215 BCE to 80 BCE	••	Copper alloy	1/6
Uncia	c. 215 BCE to 80 BCE	•	Copper alloy	1/12
Semuncia	c. 215 BCE to 80 BCE	Σ	Copper alloy	1/24

silver coin of standardized design, initially depicting the head of Roma on the obverse and the Dioscuri on the reverse. Additional silver denominations of the *quinarius* (5 asses) and the *sestertius* (2.5 asses) were also introduced. The cast bronze coinage went out of use and the struck bronze followed new designs featuring heads of deities on the obverse and a prow on the reverse. Gold coins of the denomination known as the *aureus* (25 *denarii*) were only intermittently issued and their appearance can be connected with times of crisis. They appear during the civil wars of the 80s and 40s BCE, becoming more common in the final years of the Republic.

Moneyers

Initially, the coinage was produced anonymously in the name of the Roman Republic. The appearance of living individuals on Roman coins was apparently taboo, being too resonant of kingship and the Greek model of coinage, and this initial reluctance to name individuals on coins was probably a reflection of these Republican ideals. Early Roman Republican coin designs featured deities and mythological figures, particularly those related to Rome and its foundation myths (Roma, the Dioscuri and Romulus and Remus). In the period 211 BCE–170 BCE, coins are inscribed ROMA and the *denarii* carry the head of the goddess Roma.

The individuals who issued the coins, referred to as the moneyers, were junior magistrates. They held the responsibility for minting coinage from reserves held in the Treasury at Rome. They held the office of triumvir and formed a board of three men, the *triumviri auro argento aere flando feriundo* ("three men responsible for casting and striking gold, silver, and bronze") although sometimes coins were issued by other magistrates or on the authority of the senate (marked "*EX S C*"). Their number was increased to four for a short time under Caesar. From the late second century, the moneyers had an increasing influence in the selection of designs for the coinage and their identities were more clearly marked on the coins.

The earliest issuer's marks on coins are in the form of letters, monograms, and symbols. Although the names of the individual(s) issuing the coins are usually not known in this period, they are thought to be indicated by the symbols used, sometimes in the form of visual puns. For example, the symbols of birds on coins of the moneyers Turdus (RRC 193) and Gragulus (RRC 238) (*turdus* is Latin for thrush and *graculus* for jackdaw). It was not until the mid-second century BCE that more complete names appeared on the coins and the identities of the moneyers can begin to be suggested.

It is clear that over time (and particularly from the late second century), moneyers found their role in the production of coinage to be an ideal platform for political advancement and it became more acceptable to allude to familial identity and achievements. Ancestors were named or referred

to by the choice of design used on the obverse and/or reverse. For example, the ancestral achievements of the Manlii Torquati are commemorated on coins of L. Manlius Torquatus (RRC 295/1) which feature a Gaulish torc. This is a reference to the heroic deeds of T. Manlius Torquatus in Gaul in the fourth century BCE. He is said to have slain a fierce Gaulish warrior and worn his torc, gaining the cognomen "*torquatus*" (torc) (Livy 7.10).

In time, it became acceptable to honor the living as well as more distant ancestors, and finally to allude to one's own achievements. M. Caecilius Metellus placed a Macedonian shield on his coins in 127 BCE (RRC 263/1) in reference to more recent victories of his father, Q. Caecilius Metellus Macedonicus. In 128 BCE, the aedile Cn. Domitius referred to games and corn dole potentially promised during his own office by adding a corn-ear to the obverse of his *denarius* and a small figure of a man fighting a wild beast on the reverse (RRC 261/1). These changes were accompanied by a gradual move from stylized to more individualistic portraiture, with recognizable individuals depicted.

In the late Republic, this tradition was overturned by Julius Caesar, who was the first living Roman to issue coins decorated with his own portrait. While this has been seen as an illustration of his hubris, the practice was widely adopted by others in the years leading up to the end of the Republic. During this turbulent period, coins were issued by or on behalf of the various competing political factions rather than in an official capacity for the state. Perhaps the most iconic coins from this period are the *aurei* and *denarii* issued by M. Junius Brutus celebrating the assassination of Caesar on the Ides of March 44 BCE (RRC 508). They show the cap of Liberty flanked by two daggers and the date "*EID MAR*." The coinage of Octavian (later Augustus) draws on his descent from the deified Caesar, setting the iconographic tone for what became the first Imperial dynasty.

Production

Coins were for the most part made in the mint at Rome, which is known to have been near the Temple of Juno Moneta on the Capitoline Hill; later, the goddess Moneta appears on coins as the personification of the mint. The designs on the coins were struck onto the blank flans using engraved obverse and reverse dies. The number of dies used varied according to the scale and length of production. It is clear that the supply of coinage fluctuated over time, according to demands on the state (such as the payment of soldiers and public works).

The mint was able to monitor the production of successive issues of the same design by means of a system of control marks found on *denarii* from the second to early first century BCE. These took the form of sequences of letters, numerals, and symbols (sometimes paired in relation to each other, for example, a symbol of a hare on the obverse paired with that of a hound on the reverse of a *denarius* of L. Papius, RRC 384/1).

Measures were put in place to combat forgery but this still occurred. Coins are found with a copper alloy or iron core covered in silver plating. The distinctive crimped edge of a coin known as the *denarius serratus* issued for a period from the late second century BCE may have been intended to reveal the core of a solid silver coin but plated forgeries of these still occur.

The high silver content of Roman Republican *denarii* meant that they were in circulation for a long time. They are found in British hoards of the first century CE and the "legionary series" of *denarii* of Mark Antony (RRC 544), which had a slightly lower silver content, circulated into the second century CE. It is thought that Roman *denarii* were a source of silver for the production of the British Iron Age silver coinage.

Bronze coinage was not issued throughout the Republican period, but after the late second century, it may have circulated for many years after issue (coins found are often very worn). Although the *denarius* became the standard silver coin of Spain in the first century, it appears that local issues were widely used for small change in the Roman world and imitations of Roman bronze coins could also have filled this gap in other areas. In the eastern Mediterranean, bronze coinage continued to be issued by cities now under Roman rule. These are often termed "Greek Imperial" or "Roman Provincial" coinage by numismatists (listed comprehensively in Burnett et al. 1992).

Key Issues/Current Debates

As Roman Republican coins do not bear dates, early work focused on determining the chronological sequence of types and the identities of the issuers. This dating has been influenced by the presence or absence of types in dated hoards from Italy and the Mediterranean. Sydenham published a systematic typology of the series in 1952 (Sydenham 1952). This was followed by a comprehensive study of the coinage published by Michael Crawford in his 1974 work *Roman Republican Coinage* (Crawford 1974) that set out the standard typology by which the coins are now commonly described (RRC types). The types are listed in chronological order by issue, with subtypes given to different denominations and to design variations within these.

More recent work has focused on refining this chronology. McCabe (2013) has set out a new scheme for the anonymous struck bronze coinage. New discoveries of hoards have had a significant impact on the dating of the series (notably the large Mesagne hoard (Hersh and Walker 1984) which led to revision of the dating of the issues of the mid-first century BCE (see also Mattingly 2004)). Detailed studies of certain parts of the series have appeared that draw on both archaeological and historical evidence (for example, Woytek's 2003 work on the coins of the 40s BCE). Revised dating has also had an impact on the identification of the moneyers who issued particular types; in many instances, their identity is inferred from the trajectory of their political career.

Another key strand of recent research has been the estimation of volumes of production. Die studies have provided estimates of the numbers of dies in use for particular series. The extent to which this can be related to output has been fiercely debated (see, for example, Buttrey and Buttrey 1997); the number of coins produced from each die is not known. The arguments also depend on the extent to which the production of coinage was a response to contemporary military commitments.

International Perspectives

Paris has the largest collection of Roman Republican coins (at the Cabinet des Médailles in the Bibliothèque Nationale) at over 20,000 items, including the important d'Ailly collection. Important collections of Roman Republican coins are also held in London (the British Museum), Vienna (Kunsthistorisches Museum), Hannover (August Kestner Museum), Rome (Vatican, Museo Nazionale and Capitoline Museum), Turin (Museo Civico), Madrid (Museo Arqueólogico Nacional), Naples (Museo Nazionale), Berlin (Bode-Museum), Copenhagen (National Museum), and New York (American Numismatic Society). In recent years, there has been a move toward greater accessibility of museum collections, with online databases and catalogs appearing (for example, see Ghey et al. 2010). The use of linked open data methodologies has enabled the American Numismatic Society to publish an online typology Coinage of the Roman Republic Online (CRRO) with examples drawn from many of these collections.

The study of Roman Republican coinage is not limited to the academic sphere, and many leading experts are collectors or coin dealers. The illegal trade in antiquities is an important issue for this area of numismatics (and others). It is illegal to remove archaeological material from the ground without permission in many European countries. The export of coins from many countries is restricted; recent changes in legislation also ban import of early Roman Republican coins from Italy into the USA. These measures are in place to protect the archaeological context of artifacts. This context is crucial for understanding subtleties of use and dating of archaeological material. For example, estimates of numbers of coins in circulation or the contents of hoards can be difficult to make when the scale of loss through illicit activity is not known.

In England and Wales, where metal-detecting is legal (but there is a legal obligation to report finds of coin hoards under the Treasure Act), the Portable Antiquities scheme (PAS) has had much

success in encouraging finders of ancient coins and artifacts to record their objects on an online database. The large volumes of material now recorded are a significant resource for those wishing to study geographical and chronological trends in the distribution of material over a wide area.

The International Numismatic Commission holds a major conference, the International Numismatic Congress, about every 6 years. For each conference, it publishes a Survey of Numismatic Research that gives a general overview of the subject. (For the most recent report on the Roman Republican period, see Woytek and Witschonke 2015).

Future Directions

New discoveries continue to allow refinement of chronology, and there is still scope for traditional numismatic studies focusing on chronology, typology, weight standards, and iconography. Increased understanding of these basic numismatic principles will facilitate discussion of the financial and monetary history of the Roman Republican period. Progress in these areas requires collaboration with ancient historians, archaeologists, and classicists. Scientific input is also critical for our understanding of metal sources and production techniques.

A continuation of the current focus on the distribution and chronology of hoards and site finds is likely. The past few decades have been marked by the collection and storage of such data, made possible by improved information technology. Increasingly, numismatists have been working alongside archaeologists to produce contextual studies of coinage from particular sites and regions. Such applied numismatic studies at, for example, Pompeii, have given us a more complete picture of the way in which the coinage fitted into the wider monetary systems of the Roman world (for example, demonstrating the extent of use of local bronze coinage alongside Roman silver).

There are many questions to be answered about interaction between the Roman and non-Roman worlds (for example, the imitation and use of Republican coin types outside the area of Roman authority).

Núñez Jiménez, Antonio

Racso Fernández Ortega
Departamento Disciplinas Básicas y Especialidad, Facultad de Gestión y Preservación del Patrimonio. Colegio Universitario San Gerónimo de La Habana, Grupo Cubano de Investigaciones del Arte Rupestre, La Habana, Cuba
Disciplina Arqueología, Universidad de La Habana, La Habana, Cuba

Basic Biographical Information

Núñez Jiménez was born in the town of Alquizar in the present-day province of Artemisa, Cuba, on April 20, 1923. He was awarded a Bachelor Degree in Science and Literature at the Secondary School in Havana. He had deep concern for nature, and in 1940 (Álvarez 1956), he founded the Speleological Society of Cuba, together with several young friends, including Omar Sanchez, Osvaldo Aguirre, and Arturo Díaz. This enterprise was devoted to serious investigation of the national geography of Cuba, particularly its underground landscapes.

Through public examination, Núñez Jiménez obtained the position of Geography and History teacher at the Institute of Secondary Education of Vedado in Havana. A year later he began the same task at the Central University of Las Villas "Marta Abreu." By 1956, he was accepted as a member of the National Board of Archaeology and Ethnology, the Ethnographic Society of Cuba, and the National Speleological Society in the USA.

Núñez Jiménez is a Philosophy and Literature graduate from the University of Havana. Four years later he published his *Geography of Cuba*. Dictator Fulgencio Batista's coup regime proscribed the book and prevented its circulation due to its revolutionary approach and its defense of the inhabitants of the Cuban jungle. He reached the rank of captain of the Rebel Army fighting under Commander Ernesto "Che" Guevara's orders, when the cities of Placetas and Santa Clara were taken. After the 1959 revolutionary triumph, he held important governmental positions as director of the National Institute of Agrarian Reform and the INRA magazine, he was appointed president of the National Bank of Cuba in 1960, and he was founder and president of the Cuban Academy of Sciences (1962–1972). In 1981, he achieved the PhD degree in Geographical Sciences issued by the "Lomonosov" Moscow State University, in the Union of Soviet Socialist Republics (USSR) (Martín 2008).

He was appointed Cuban ambassador in Perú between 1972 and 1979. Yet, he continued his archaeological work and recorded and documented rock art, visiting 72 stations in places between the borders of Chile and Ecuador and between the Pacific Ocean and the Eastern foothills of the Cordillera de los Andes; he was accompanied by recognized Peruvian archaeologists like Dr Eloy

Linares Málaga and Dr Rogger Ravines; this work ended up with the publication of Petroglyphs of Peru: World Panorama of Rock Art and the offprint, *The Stone Book of Toro Muerto*. In 1979, when he was vice minister of culture, he created the National Commission of Monuments, of which he was the president until his death. There, he encouraged the writing and enactment of the legislation to safeguard the cultural and natural heritage.

Major Accomplishments

Towards 1945, Núñez Jiménez organized a geographic expedition to the east and far east regions of Cuba, carrying out studies that contributed to the fields of geography, archaeology, and speleology. The highest point of Cuban topography is reached at Turquino Peak, and Suecia Peak, the third highest peak, was reached for the first time, while the Toa River was also explored. Due to a number of different visits to Seboruco rocky peaks from 1939, Núñez Jiménez was able to discover the oldest archaeological remains found until that time. This marked the beginning of research into the 6000-year-old Seboruco culture. In 1951, Núñez Jiménez graduated in Philosophy and Literature from the University of Havana. Four years later he published his *Geography of Cuba*. Dictator Fulgencio Batista's coup regime proscribed the book and prevented its circulation due to its revolutionary approach and its defense of the inhabitants of the Cuban jungle.

Núñez Jiménez was a bold researcher; he devoted long hours to the exploration of caves and valleys, mountains and rivers, underground water sources, and flora and fauna. His incessant work made him a member of several expeditions to the North Pole in 1972 and Antarctica in 1982. He also explored rock stations in Colombia, the Dominican Republic, the Bahamas, other islands of the Caribbean, as well as the Pascua Islands. In 1987–1988, he organized and directed the expedition "Canoeing from the Amazon River to the Caribbean," in which he travelled more than 17,400 kilometers and visited 20 countries of the Amazon and Orinoco basins and the Antilles Sea researching in the fields: rock art, speleology, karstic studies, archaeology, and history.

He lectured in several universities all over the world and received important international degrees and qualifications such as Dr *Honoris Causa* of the Central University of Ecuador; Honorary Professor of the Autonomous University of Santo Domingo, Dominican Republic; and Honorary Member of the Geographical Society of the Union of Soviet Socialist Republics in 1963. He was a member of the Czechoslovak Academy of Sciences and of the Venezuelan Societies of Speleology and Natural Sciences; he was also the founding president of the Speleological Federation of Latin America and the Caribbean and member of the National Geographic Society of the USA (Martín 2008).

Among his most important books, the following could be mentioned: *Twenty Years Exploring Cuba*, which is the documented history of the Speleological Society of Cuba (SEC) until 1961. *Cuba, with the Backpack on the Shoulders* (Ediciones Unión, La Habana, 1963) describes some expeditions carried out by the SEC. *Caves and Pictographs* (Edición Revolucionaria, La Habana, 1967) presents speleological and descriptive studies of the García Robiou and Ambrosio caves' pictograms in the provinces of Mayabeque and Matanzas, respectively (Fernández and Calzada 2012). *Cuba: Rock Art* (Editorial Científico Técnica, La Habana and Industrial gráfica S. A., Lima, 1975) has become a classic text to know the state of the art of this specialty. *Rock Art of Cuba* (Jaca book, Turin, 1985) is a picture gallery of some of the most representative stations of the country. Petroglyphs of Peru: World Panorama of Rock Art (Editorial Científico Técnica, La Habana, 1986) and *Canoeing from the Amazon River to the Caribbean* (Editorial El Conejo, Quito, 1989) are an account of the route and the places visited by the expedition. *Half a Century Exploring Cuba* (Imprenta Central de las FAR, La Havana, 1990) compiles the actions of the SEC between 1961 and 1990 (Fernández and Calzada 2012).

Núñez Jiménez was an extraordinary person and a pioneering researcher. He passed away at the age of 75 years on September 13, 1998, in the city of La Havana, leaving a remarkable legacy for present and future generations.

Núñez, Lautaro

Isabel Cartajena
Department of Anthropology, Universidad de Chile, Santiago de Chile, Chile

Basic Biographical Information

Lautaro Núñez Atencio was born on January 24, 1938, in Iquique (Fig. 1). He came from a family of Spanish origin that had settled in the oasis of Pica, Tarapacá, in the seventeenth century and from a local mestizo line dating back to the nineteenth century. Although he lived in Iquique, he spent long summers with his family in Pica, where as a young boy he experienced the caravans that came to Tambo del Resbaladero run by his aunt, Luisa Núñez. The caravans that he witnessed not only brought charqui, ropes, woven items, quinoa, potatoes, and liquor, among many other goods; they also were accompanied by children, who spent several years in Pica before returning to their homes.

In Iquique he lived in El Morro, a neighborhood populated by local fishermen. With Juan Varela, who would later become a geologist and close collaborator in Lautaro's Paleo-Indian investigations and other friends, he founded the Huracán Explorers Club. This group of 12–17-year-old adolescents went on several excursions to climb the peaks of the Coastal Range, Pica and Tarapacá, camping near shell middens and cemeteries, relying on freshwater springs and coastal resources, forging a close link with the natural world. Academically, Lautaro was deeply influenced by the engineer Bertie Humberstone, the son of James "Santiago" Thomas Humberstone, founder of northern Chile's modern saltpeter industry. Bertie was a kind of philanthropist who invited children from the local school to his house in the afternoons, where they had access to his extensive library. It was on these visits that Lautaro first encountered the scholarly world of archaeology.

It is difficult to tell exactly how these early influences – his exposure to the ethnic world, the nature and its resources, and the study sessions at Bertie Humberstone's home – marked the young Lautaro, but with no doubt contributed in his decision to travel to Santiago to study history and geography at the Universidad de Chile (as at the time no archaeology programs existed in our country). In 1960 he became a research assistant at the Universidad de Chile's Center for Anthropological Studies and in 1962 was appointed director of the Museum of Calama and established the Program in Archeology and Museums at the Universidad de Chile, Zona Norte. His interest in early sites, chronology, and stratigraphy led him to the Univerzita Karlova in Prague between 1968 and 1969, where he worked on large Paleolithic sites and also married Drahomíra Srytrova, an academic with a Masters in History.

In April 1974, in the midst of intense social unrest in Chile, Lautaro was dismissed from his post for political reasons and the Archeology and Museums Program was suspended meanwhile the campuses of the Universidad de Chile Zona Norte were shut down. In January 1975 he joined the Universidad Católica del Norte and in 1984 he co-founded the Institute of Archeological Research and Museum (*Instituto de Investigaciones Arqueológicas y Museo*, IIAM),

Núñez, Lautaro, Fig. 1 Lautaro Núñez at his laboartory in San Pedro de Atacama

serving as its director for two terms. Today, he works as a researcher at IIAM and is a professor in the Masters' and Doctoral Program offered jointly by the Universidad Católica del Norte and the Universidad de Tarapacá.

Major Accomplishments

His first excavations were in northern Chile, in the Tarapacá ravine, and were carried out with D. True as part of an agreement between the Universidad de Chile and the University of California. These were Lautaro's first approaches to formative societies, and it quickly triggered his interest in the history of the processes that had led to their increasing complexity.

Upon his arrival in San Pedro de Atacama, he began a research program through the Archeological Museum. The work was financed by the Paleo-Indian Program of the Smithsonian Institution with the support of Betty Meggers and Clifford Evans and sponsored by R. P. Gustavo Le Paige, Director of the Archeological Museum, with whom Lautaro formed an abiding friendship. His study of the Paleo-Indian sites of Tagua Tagua and Quereo marked the beginning of his multidisciplinary approach, which would lead to collaborations with professionals in many fields, including his childhood friend, Juan Varela, who as a geologist accompanied Lautaro on several excavations along with specialists in paleontology and bioanthropology, among other disciplines.

At the same time, he explored other areas of interest such as caravan traffic and the relations between routes and geoglyphs. As an outcome of a conversation held with Tom Dillehay during the VII National Congress of Chilean Archeology, which was held in Alto de Vilches in 1977, the book *Movilidad Giratoria, armonía social y desarrollo en los Andes Meridionales: Patrones de tráfico e interacción económica* was conceived (Núñez and Dillehay 1979). Convinced that caravan traffic was crucial to an understanding of Andean prehistory, Lautaro pursued a Doctorate in this subject from the University of Tokyo, completing his thesis *Tráfico de complementariedad de recursos entre las tierras altas y el Pacífico en el área Centro Sur Andina*.

As a consequence of the connection he established with Dr. Martin Grosjean of the University of Bern, Switzerland, his investigations took on a new dimension: the environment. The reconstruction of the environment had always been an important element of Lautaro's work, especially in relation to early settlements, but through his research at Puripica, he sought to analyze specifically the relationship of human groups to their environment. This was the starting point for the understanding of the paleoclimatic

history of the study area; it would be followed by several interdisciplinary projects that significantly expanded the existing knowledge of human occupations in the desert environments of the western slope of the Atacama Puna region. By means of a large occupational sequence that began c. 12,000 BP, it was possible to model the relationship between human occupations and paleoenvironments. This work demonstrated the need to understand those extreme environments, where the scale and the effects of environmental variations may cause different impacts, even on microenvironments within the same region (ecorefuges) and therefore on the human groups residing there.

Lautaro Núñez always defended the autochthonous thesis, which holds that the trajectory of a society can be understood as the result of local processes deeply rooted in the archaic period. He obtained convincing support for his ideas as a result from his work at Quebrada Tulán from the late 1970s onwards, from the discovery of a large ceremonial center (Tulán-54) comparable to the earliest ones of the Circumpuna Andes and from his understanding of animal domestication centers beyond the Central Andes, among others. He believed that the particularity of formative societies could only be understood by acknowledging the early importance of exchange and interaction networks and the combined social, ritual, productive, and environmental factors that existed in each region.

The versatility of Lautaro Núñez's work makes it difficult to synthesize his many areas of interest and contributions to the field of archaeology. But these interests and contributions do share some common elements, including a strong emphasis on temporal dimension, the interdiscipline, and the need for an analytical framework firmly grounded in anthropological and ethnographic knowledge of the Andean world.

Professional Awards and Honors

During 2002 the government of Chile awarded Lautaro Núñez the National History Prize in recognition of his lifetime achievement. In 2012, in recognizance of his academic and investigative work, the Universidad Católica del Norte granted him the honorary degree of doctor honoris causa and published a book in his honor, entitled *Temporalidad, interacción y dinamismo cultural* (2011).

Lautaro Núñez's interest in our heritage – not only the archaeological but the anthropological and historical as well – led him to write several books for a wide audience. These include the popular religious practices of Tarapacá (*La Tirana del Tamarugal: del misterio al sacramento*, 1989) and on Tarapacá's society (*The evolution of a valley population and resources of Tarapacá over a Milennium*, 1986). Others focused on the impact of the Spanish conquest on the Americas (*Fiesta en la Antípoda: Reflexiones sobre el ocultamiento de América*, 1993) and also one that invited children to learn about the archaeologist's work (*Aprendamos arqueología en nuestra tierra*, 2001). This body of work not only earned Lautaro the recognition and respect of his academic colleagues but also led to him being declared an illustrious son of the city of Iquique (2003) and of Pica (2003), his places of origin.

Lautaro's work enjoys widespread international recognition, demonstrating the heights that can be attained by archaeology in the Southern Cone of America. Lautaro Núñez was a pioneer in that field and has encouraged its expansion through his interactions with colleagues in Argentina, Peru, and Bolivia.

Nuragic Culture and Architecture (Bronze Age to Iron Age)

Emily Holt
Department of Classics, Miami University, Oxford, OH, USA

Introduction

The term "Nuragic" refers to an extensive, shared material culture that developed on the island of Sardinia beginning in the Early or Middle Bronze Age and continued at least through the Early Iron Age. Most visibly, the societies of the Nuragic culture shared a distinctive type of architectural construction: megalithic stone towers called *nuraghi* (sg. nuraghe). Archaeologists estimate that over ten thousand nuraghi once existed throughout Sardinia, although now only a few thousand are extant. In addition to the nuraghi, Nuragic societies shared other types of material culture. Similarities in the construction of tombs and cult places as well as in ceramic styles, agricultural and food processing equipment, and household objects all indicate a high degree of interaction among Nuragic societies. Although the nature of this interaction is not fully understood, it probably included trade, intermarriage, and shared rituals and may also have involved intergroup raiding and conflict.

Although the Nuragic culture developed autochthonously from earlier Neolithic and Eneolithic cultures and is unique to the island of Sardinia, similarly megalithic Bronze Age cultures developed simultaneously on Pantelleria, Corsica, the Balearic Islands, and the Iberian mainland, suggesting that the development of the Nuragic culture was part of broad changes affecting much of the West Mediterranean (cf. Blake 2001). The Nuragic culture had important connections with the East Mediterranean as well, and a variety of East Mediterranean imports have been found in excavations of Nuragic contexts.

Definition

The Nuragic culture is named after its characteristic form of architecture, the nuraghe. Nuraghi are monumental, dry masonry structures that use multistory towers in the shape of truncated cones as the basic unit of building. The first appearance of the term *nuraghe* in writing is an inscription on the lintel of Nuraghe Aidu Entos in Bortigali (Webster 2016: 2–3). The inscription is dated to the first century CE on epigraphic grounds, but the word itself does not have Indo-European roots. It is thought to be the original Bronze Age word for the towers (Lilliu 1959: 32), and some scholars use the word as a name for the Nuragic people themselves, calling them the Nur (Webster 1996: 22, 2016: 4). Although this can be a useful shorthand, it should be remembered that "Nur" is a modern coinage that may suggest more ethnic unity than the Nuragic culture actually had.

Key Issues

Architectural Overview

The earliest Nuragic structures are the corridor nuraghi, sometimes called proto-nuraghi or pseudo-nuraghi. These are monumental dry masonry platforms, each with one or more narrow corridors running through them. They often have small, roughly circular, or elliptical rooms branching off of the corridors (see Lilliu 1982: 13–29). Housing structures were built on top of these platforms, and food or livestock were probably kept in the corridors and small rooms below. Few radiocarbon dates exist for corridor nuraghi, and those that do exist have error ranges so broad as to be unhelpful in dating their period of construction. Corridor nuraghi are generally dated on the basis of pottery to the Early (c. 2000–1700 BCE) or Middle Bronze Age (c. 1700–1365 BCE).

The funerary architecture that accompanies the corridor nuraghi elaborated on the earlier traditions of the Eneolithic: cist graves, dolmens, and especially passage graves. The early Nuragic people added a curved forecourt to the plan of the passage grave to create a new kind of funerary architecture traditionally called giants' tombs (*tombe di giganti*) (Fig. 1). The forecourts of the giants' tombs were originally constructed of stele, and the central stela was often carved with a door motif and contained an opening through which offerings could be made to the dead. Forecourts were the locus for feasting rituals. Many early Nuragic giants' tombs were constructed *ex novo*, but in several instances, earlier passage graves were elaborated into giants' tombs, including the sites of Su Cuaddu de Nixìas (Lunamatrona), Li Lolghi (Arzachena), and Coddu Vecchiu or Capichera (Arzachena). Examples of cist graves and dolmens that were transformed into giants' tombs are rarer but do exist.

Nuragic construction techniques improved during the Middle Bronze Age with the discovery of how to build false tholos and true tholos chambers, beehive-shaped false domes constructed by stacking successively smaller rings of stone blocks (see discussions in Lilliu 1982: 30–61; Webster 2016: 46–51). Many corridor nuraghi were then elaborated and expanded into more complex structures that included false tholos and tholos nuraghi; this continuity of occupation can be seen at numerous sites in Sardinia such as Sa Fogaia (Siddi), Su Mulinu (Villanovafranca), and Santa Vittoria (Serri). Thousands of new Nuragic sites were also constructed at this time. Many of the sites were single towers, often called simple nuraghi. Others were multitower or complex nuraghi: two or more attached towers which frequently included an attached, walled courtyard (Fig. 2). Some sites that were founded at the end of the Middle Bronze Age developed into nuragic complexes, with multitower nuraghi at their centers surrounded by circumference walls, additional towers, and villages. Nuraghe Su Nuraxi (Barumini) and Nuraghe Arrubiu (Orroli) are two of the best known (Fig. 3).

The construction of giants' tombs also changed during the Middle Bronze Age, drawing on the improved architectural techniques of the tholos nuraghi. The orthostatic stele construction was

Nuragic Culture and Architecture (Bronze Age to Iron Age), Fig. 1 Front (*left*) and side (*right*) views of Sa Dom' e S'Orcu (Siddi), a giants' tomb in the later, coursed-stone construction style. (Photos E. Holt)

Nuragic Culture and Architecture (Bronze Age to Iron Age), Fig. 2 Nuraghe Santu Antine (Torralba), a multitower nuraghe with a central tower, courtyard, and three surrounding towers. (Photo E. Holt)

Nuragic Culture and Architecture (Bronze Age to Iron Age), Fig. 3 The Nuragic village surrounding Nuraghe Su Nuraxi (Barumini). (Photo E. Holt)

replaced by courses of stones inclining toward an arched ceiling, and the central stela with door motif was replaced by a simple opening with a stone architrave between the two wings of the forecourt (see Castaldi 1969; Blake 2001).

During the Late (c. 1365–1175 BCE) and Final Bronze Age (c. 1175–1020 BCE), successful sites such as Nuraghe Su Nuraxi and Nuraghe Arrubiu were elaborated into important centers with the addition of new walls and towers; however, the basic Nuragic construction techniques remained the same. Architectural innovation during this period came in the form of cult architecture, and the well temple or sacred spring (*pozzo sacro*) was established. These well temples utilized the tholos construction technique of the nuraghi to create

Nuragic Culture and Architecture (Bronze Age to Iron Age), Fig. 4 The entrance (*left*) and staircase (*right*) of the well temple of Santa Cristina (Paulilatino). (Photos E. Holt)

underground, vaulted chambers over naturally occurring springs. Well temples include some of the finest architecture built during the Nuragic period, and the well temple of Santa Cristina (Paulilatino) is a particularly impressive example (Fig. 4). Well temples were the sites of important Nuragic ritual and remained in use for centuries, continuing to receive votive offerings well after the end of the Nuragic culture.

During the Final Bronze Age and Early Iron Age (c. 1020–900 BCE), an important change occurred in the construction and use of Nuragic architecture. The existing nuraghi were allowed to collapse, and it is generally though not universally accepted that no new nuraghi were constructed after the Final Bronze Age (see Webster 2016 for a dissenting view). Many nuraghi fell out of use, and those that remained in use were treated as ritual spaces, taking on a ceremonial function they had not previously had (Perra 2013: 166–171). Villages were built around some nuraghi that had not previously had villages, sometimes utilizing stones from the collapsed nuraghe itself. Even the floor plans of the Early Iron Age houses were different from those of the Bronze Age. Bronze Age houses tended to be circular in plan, but the houses of the Early Iron Age were composed of many subcircular and subrectangular rooms around an open courtyard. Evidence excavated from the Early Iron Age village of Genna Maria (Villanovaforru) indicates that these rooms had distinct functions, unlike the undifferentiated space in Bronze Age houses. The new Iron Age villages also differed from their Bronze Age predecessors by being open-air villages lacking fortifications and circumference walls. Funerary architecture also changed in the Iron Age. Communal burial in giants' tombs began to give way to individual burial, such as the famous burials at Monti Prama (Cabras).

Socioeconomic Overview

The complex architectural history of the Nuragic culture with its development, elaboration, and periodic innovation indicates complex and changing socioeconomic structures. However, scholars disagree about the amount of social hierarchy present in Nuragic society when the first corridor nuraghi, giants' tombs, and tholos nuraghi were built. Some see the corridor nuraghi and single-tower nuraghi (Fig. 5) as evidence of an egalitarian society with a family-level organization (Webster 1996: 71, 96) and interpret the giants' tombs as having the same community burial function that passage tombs appear to have had in the Eneolithic. Other scholars interpret corridor nuraghi as early signs of

Nuragic Culture and Architecture (Bronze Age to Iron Age), Fig. 5 A single-tower nuraghe at Santa Cristina (Paulilatino). (Photo E. Holt)

developing hierarchy and question whether burial in the restricted space of the giants' tombs was, in fact, open to all members of society (Bernardini 2010).

In spite of the disagreements about the beginnings of Nuragic society, scholars tend to agree that by the Late and Final Bronze Age, Nuragic society had a stratified organization with privileged leaders controlling production. Many scholars see the Early Iron Age cultural transition indicated by the abandonment of the nuraghi; the construction of large, open villages; and the move away from giants' tombs toward individual burials as evidence of a codified social hierarchy (Van Dommelen 1998: 79, 105; Perra 2009). An alternative hypothesis suggests that, toward the end of the Nuragic culture, power fell out of the hands of the ruling aristocracy and into the hands of religious leaders (Campus et al. 2010: 62–8).

Carved reliefs from Medinet Habu, the mortuary temple of Rameses III in Luxor, Egypt, may show Nuragic warriors as part of an influx of Sea Peoples that was successfully repulsed c. 1200 BCE. The identification of these warriors as Nuragic is based on stylistic similarities between the helmets they are shown wearing and the helmets worn by warriors in bronze figurines produced by the Nuragic culture in the Final Bronze and Early Iron Age. This evidence may indicate that Nuragic people took part in the widespread, armed migrations that occurred at the end of the Mediterranean Bronze Age.

In general, the subsistence economy of the Nuragic people seems to have been similar to that of other Bronze Age Mediterranean cultures. The Nuragic people grew wheat and barley; raised sheep, goats, and pigs; used cattle for traction and periodically meat; and hunted, fished, and gathered according to the locally available resources (cf. Perra 2010). However, we know next to nothing about the specifics of farming and herding strategies, systems of land tenure, or the social aspects of production and storage. One important difference from other Mediterranean Bronze Age economies is that there is currently no evidence for the presence of the horse in Bronze Age Sardinia. This absence, if real, will have limited travel times, communication, and certain kinds of elite competition.

Craft production in Nuragic society is difficult to reconstruct. As often happens, we are left with abundant evidence of the most durable products and know little about the rest. Spindle whorls are frequent finds on Nuragic sites, indicating textile production, and impressions left on some types of Nuragic pottery attest to the weaving of mats and

baskets. Ceramic production came in a variety of shapes for serving, cooking, and storage and became more refined as the Nuragic period progressed. Slag, stone molds, and copper ingots of different shapes attest to a developed bronze working industry at an early stage of the Nuragic culture (see Lo Schiavo et al. 2005), though deposition of bronze artifacts did not occur in any great quantity until the Final Bronze and Early Iron Age. Numerous figurines of humans and animals, known as *bronzetti*, have been recovered from later Nuragic sites, though very few have any contextual information attached. Other common Nuragic artifacts are bone awls and pins, river pebbles used to burnish pottery, and fine sedimentary stones for sharpening metal tools. Obsidian, which is available on the island, remained an important resource for toolmaking, as it was in the Sardinian Neolithic.

The people of the Nuragic culture also participated in extensive extra-insular trade networks. Trade during the Middle, Late, and Final Bronze Age tended to be with the East Mediterranean. Numerous finds of Mycenaean and Cypriot artifacts in Sardinia include a Late Helladic IIIA2 alabastron from Nuraghe Arrubiu (Orroli), Mycenaean ceramics from Nuraghe Antigori (Sarroch), a carved hippopotamus ivory figurine from the Nuragic village Mitza Purdia (Decimoputzu), and fragments of oxhide ingots from numerous sites throughout the island (Giardino 1992). Recent work in ceramic petrography and composition studies has expanded our knowledge of Nuragic trade, identifying imports from a greater number of locations than was previously recognized as well as Nuragic ceramics that were exported to the East Mediterranean (Karageorghis 2011; Lo Schiavo 2012). Additionally, recent research in lead isotope analysis suggests that Nuragic bronze reached as far north as Scandinavia during Sardinia's Middle through Final Bronze Age (Ling et al. 2014).

At the end of the Final Bronze Age and the beginning of the Early Iron Age, people on Sardinia seem to have traded less with the East Mediterranean and focused more on the West Mediterranean and mainland Italy. The Nuragic people exchanged ceramics, weapons, and *bronzetti* with the societies of Etruria and the Iberian Peninsula.

Current Debates and Future Directions

Numerous important issues are currently being debated in the study of the Nuragic culture, the most fundamental of which is probably that of chronology. At present, the number of radiocarbon and dendrochronological dates for the Nuragic culture is small compared to the number of excavated sites, and much of the dating of settlement types, ceramic styles, and architectural changes is conventional. Two different perspectives on Sardinian chronology have therefore developed (see Van Dommelen 1998: 55). The first perspective, associated with historical and classical archaeology on Sardinia, relies primarily on textual and epigraphic evidence and on art historical comparison between Sardinian artifacts imported from the Aegean and Near East and similar artifacts found in datable contexts in the East Mediterranean. The second perspective, associated with prehistoric archaeology on Sardinia, bases its chronology on dendrochronology and radiocarbon dating (cf. Tykot 1994; Manning 1998).

A second fundamental discussion in Nuragic archaeology addresses what was the purpose of the nuraghi, a discussion that is fundamentally tied to understanding the structure and interactions of the numerous societies that made up the Nuragic culture. That the nuraghi had a primarily domestic function is no longer in doubt (cf. Blake 2001: 146), but whether the nuraghi also served a defensive function is debated. The massive walls of the nuraghi and their enclosed courtyards suggest a protective function, as does the placement of many Middle Bronze Age nuraghi in high, defensible locations with good views of the surrounding territory. The existence of circumference walls around many Nuragic villages may also indicate that defense was a concern.

However, the overbuilt, megalithic nuraghi may have served as displays of power and authority rather than as actual defensive structures. Many scholars point out that the usual archaeological indications of conflict, such as human skeletons showing violent trauma and evidence of the periodic destruction of settlements, are missing from Nuragic society (Campus et al. 2010: 67).

Archaeologists' ability to settle this debate is currently hampered by a lack of information about Nuragic settlement systems. Although the spatial relationships among visible monuments have often been studied (Trump 1990; Blake 2001; Cossu and Perra 2008), few excavations and field surveys have explored these relationships in depth. In addition, useful information about Nuragic populations is difficult to obtain because most giants' tombs were looted or reused in antiquity, destroying their contents. Without a more detailed understanding of the relationships among complex nuraghi, simple nuraghi, villages, and tombs, it will remain difficult to understand all the functions the nuraghi may have had.

Finally, there is an important debate that centers around what happened to the Nuragic culture. Some scholars see the events of the Final Bronze Age and Early Iron Age as indicating reorganization and change, resulting in a different Sardinian culture during much of the Iron Age (see Van Dommelen 1998: 76–9, 101–3; Perra 2013: 166–210). Other scholars read the continuity of Nuragic craft styles and the continued occupation of Nuragic sites as evidence for cultural continuity well beyond the Early Iron Age, continuing to use the word "Nuragic" to describe Sardinian society as late as the Punic (Lilliu 1982), Roman (Webster 1996), and even Medieval periods (Dyson and Rowland Jr. 2007).

Although much important work has been done on the archaeology of the Nuragic culture, the current state of the field invites substantial future research. New excavations and surveys, particularly projects investigating a wider range of settlement types and projects focusing on the early development of the Nuragic culture, will help resolve many of our unanswered questions about the structures and interactions of Nuragic society. The collection of new radiocarbon dates will continue to refine our knowledge of Nuragic chronology. Some projects have already begun the process of reconstructing the Nuragic environment (Ruiz-Gálvez 2005), but the need to contextualize the Nuragic economy within its resource base and natural surroundings warrants considerable further study. Finally, archaeometric techniques such as ceramic petrography are opening up exciting new avenues of research. As a field of inquiry, Nuragic archaeology has great potential for growth and development.

Nzewunwa, Nwanna

Emuobosa Akpo Orijemie
Department of Archaeology and Anthropology, University of Ibadan, Ibadan, Nigeria

Basic Biographical Information

Information on this yet-to-be-celebrated archaeologist is surprisingly quite few. From the few articles about him gleaned for this work, it was observed that he was a field archaeologist. Nzewunwa believed, and rightly, that excavation and field surveys are the principal tools of archaeology (Nzewunwa 1983). Dr. Nzewunwa obtained a B.Sc. in African Archaeology and History from the University of Nigeria, Nsukka, in 1973 and went on to the University of Cambridge, England, for a Ph.D. He earned this Ph.D. in 1979; his thesis is titled "*Aspects of Economy and Culture in the Prehistory of the Niger Delta*."

Major Accomplishments

Nzewunwa was an accomplished field archaeologist. Beginning from the early 1970s, he successfully organized, both single-handed and jointly, archaeological excavations in Nigeria particularly in the Middle Niger Valley and in the Niger Delta areas (Nzewunwa 1980, 1983). He also participated in field research works in Britain, Denmark, France, and Germany. In 1981 he was appointed Chairman of a three-man task force committee by the Archaeological Association of Nigeria (AAN) to produce a brochure on tourism in Nigeria. It was while serving in this committee that he got the inspiration to produce an enduring material to serve as a guide to available archaeological sites at that time. In 1983, he published the book titled *A Sourcebook for Nigerian Archaeology*; this book is still unparalleled in Nigeria today.

After obtaining his Ph.D. degree, Dr. Nzewunwa served as a Junior Fellow at the University of Nigeria, Nsukka, and later became a lecturer at the University of Jos (Nzewunwa 1983). Perhaps on the invitation of one of Nigeria's legendary historian – Prof. E.J. Alagoa – he finally moved to the University of Port Harcourt as a Senior Lecturer. While in Port Harcourt, he had several joint projects with Profs. E.J. Alagoa, F.N Anozie (of blessed memory), and Mr. (now Prof.) Abi Derefaka. A major product of such collaboration is the 1987 book: *The Early History of the Niger Delta* jointly edited by E.J. Alagoa, F.N. Anozie, and N. Nzewunwa. He had in 1980 published the book *The Niger Delta: Its Prehistoric Economy and Culture*.

Dr. Nwanna Nzewunwa had about ten publications in journals, books, and chapters in books until his unfortunate and untimely death. His demise, which occurred at the prime of his career, was a rude shock to the AAN and NCMM. Although the exact date of his death could not be ascertained, the event would have occurred shortly after his last major publication in 1983.

O

O'Connor, Susan

Sally Brockwell
Australian National University, Canberra, ACT, Australia

Basic Biographical Information

Professor Susan Lillian O'Connor gained her BA (Hons, 1st class) in archaeology from the University of New England in 1980 and her PhD from the University of Western Australia (UWA) in 1991. She worked as a lecturer and researcher at UWA until 1994 and joined the Australian National University (ANU) in the same year as Research Fellow in the Department of Prehistory, Research School of Pacific and Asian Studies, now the Department of Archaeology and Natural History. She was Head of Department between 2005 and 2012 and was promoted to Professor in 2008 and in 2012 was made an Australian Research Council (ARC) Laureate Fellow and Distinguished Professor at ANU.

Major Accomplishments

Sue's wide research interests include the archaeology of Australia and Southeast Asia, coastal and island archaeology, maritime colonizations of Island Southeast Asia and Australia and the links between these regions, interactions between humans and their environment, Southeast Asian rock art and rock art dating, the Neolithic transition in Southeast Asia, and technological change, innovation, and transmission theory. Sue is a dedicated fieldworker often working in remote locations under difficult conditions, e.g., in Arnhem Land, the Kimberley, Indonesia, Papua New Guinea, and Timor-Leste. She has a special interest in the archaeology of the Kimberley region that spans over 25 years from her PhD research, and she has continued to pursue active research in that region. Her thesis was entitled: *A Prehistory of the Islands of the Buccaneer Archipelago and Adjacent Mainland West Kimberley, Western Australia*, and concerns the nature of Pleistocene colonization and changes in occupation from the late Pleistocene through to the late Holocene (O'Connor 1999). In 1993 she was awarded an ARC grant to investigate the antiquity of occupation and cultural transformations in hunter-gatherer societies in the Oscar Napier Ranges. This project provided the first evidence of Indigenous occupation of the Kimberley region dating back over 40,000 years, as well as the earliest evidence for rock art production in Australia (O'Connor 1995; O'Connor and Fankhauser 2001). She has continued her research interests in Western Australia with ARC projects on the effect of catastrophic marine inundation events on the archaeological record of the Pilbara and Kimberley coastline with Anthony Barham and Stewart Fallon (ANU) (Barham and O'Connor 2007), on the lifeways of the first colonists in the

Kimberley region with Jane Balme (UWA) and Moya Smith (Museum of Western Australia) (Balme and O'Connor 2014), and in nearby Arnhem Land in the Northern Territory, working on contact period sites with Daryl Wesley (formerly ANU, now Flinders University) (Wesley et al. 2016).

Sue has always worked closely with Indigenous communities and has undertaken an Australian Institute of Aboriginal and Torres Strait Islander Studies funded joint initiative with the Worrorra community to record rock art and assess the impact of cultural tourism on sites in their country in the coastal west Kimberley (O'Connor et al. 2008). Overseas, Sue has worked on projects in Indonesia, Papua New Guinea (PNG), and Timor-Leste and was one of the first archaeologists to work in Timor-Leste after its independence. Her reassessment of the Neolithic transition holds major implications for our understanding of cultural/technological transmission between PNG/Island Melanesia and Island Southeast Asia in the early-mid Holocene (O'Connor 2006). She has discovered and excavated high profile Pleistocene sites, including Jerimalai and Laili in Timor-Leste; at 42,000 and 45,000 years old, they are the earliest site occupied by modern humans in Island Southeast Asia and contain the oldest evidence for pelagic fishing in the world (Hawkins et al. 2017; Marwick et al. 2016; O'Connor 2007; O'Connor et al. 2011). Excavation of the Pleistocene site of Makpan on Alor Island in Indonesia uncovered the world's oldest known fishhooks placed in a burial ritual, dated to 12,000 years: http://chl.anu.edu.au/news-events/news/915/distinguished-professor-sue-oconnor-finds-worlds-oldest-funereal-fish-hooks.

Sue has always been open to collaboration with colleagues from a diverse range of disciplines leading to innovative research, reflected by her successful research grants and publications. She recently completed several ARC projects in Island Southeast Asia, on indigenous fortifications and climate change in East Timor with anthropologist Andrew McWilliam (formerly ANU, now Western Sydney University) (O'Connor et al. 2012), rethinking the interaction between culture and nature in the management of cultural heritage with Denis Byrne (then Office of Environment and Heritage, New South Wales Government, now Western Sydney University) (Brockwell et al. 2013), and in Sulawesi investigating modern human colonization across our region with Ben Marwick (University of Washington) and Emma St Pierre (University of Queensland) (Aplin et al. 2016). In 2012 she won the ARC's most distinguished award, a Laureate Fellowship, to research modern human dispersal and behavioral complexity from a Wallacean and Australian perspective. She has continued to pursue this theme as part of the team that in 2017 won the ARC Centre of Excellence for Biodiversity and Heritage, based at Wollongong University: https://epicaustralia.org.au/team/susan-oconnor/.

Sue has published over 100 articles and 5 books, including O'Connor (1999), O'Connor and Veth (2000), O'Connor et al. (2005), Fairbairn et al. (2009), and Brockwell et al. (2013). As well as her outstanding research and publication record, she has made numerous other contributions to archaeology, as a teacher, editor, reviewer, examiner, consultant, committee member, and tireless promoter of Australian archaeology, both here and internationally through conference organization, numerous presentations, and media interviews. She has an excellent record of graduate completions and her past students include a principal heritage advisor with Rio Tinto; a CEO with the Department of Foreign Affairs and Trade; a former advisor to the National Directorate of Culture in Timor-Leste, now employed by UNESCO in Afghanistan; and a number of academics who hold university positions at ANU and the Universities of Cambridge, Flinders, Griffith, Queensland, University of Technology Sydney, Washington, Wisconsin, and Wollongong. Her outstanding contributions to the discipline were recognized in 2007 when she was elected Fellow of the Australian Academy of the Humanities (FAHA) and the Society of Antiquaries of London (FSA). In 2009 her efforts were rewarded by ANU when she was awarded two Vice-Chancellor's awards for staff excellence and excellence in supervision and in 2012 when she was promoted to the ANU's highest level of professorship. In 2011 she

received the Rhys Jones Medal, the highest honor awarded by the Australian Archaeological Association.

Oceania: Historical Archaeology

Ian Smith
Department of Anthropology and Archaeology, University of Otago, Dunedin, New Zealand

Introduction

Oceania is a vast region containing many thousands of islands that entered the modern world along a diverse range of trajectories over a period of about four centuries. Only a small proportion of these islands have seen archaeological investigations focused on this period. Where it has occurred, this research has generally concentrated on either the recent past of indigenous oceanic societies or on those of new settler communities,

with a small number of studies exploring the middle ground of new social and community identities forged through the engagement of these two worlds.

Definition

Oceania is centered on the tropical and subtropical islands of the Pacific Ocean. Precise definitions of its boundaries vary, but the term is used here to encompass the islands of Melanesia, Micronesia, and Polynesia (Fig. 1). Prehistoric human settlement had begun by c. 40 kya in the west but did not reach the southern margins of Polynesia until the thirteenth century CE. European encounters with Oceania began in 1521 with the Spanish in Guam and 4 years later the Portuguese in Yap. Following the establishment of a Spanish colony in the Philippines to the west of Oceania in 1565, regular passage of Manila galleons between there and Mexico led to sporadic encounters throughout northern parts of Oceania, which were extended southward by Spanish and Dutch explorers during the seventeenth century. However, the vast majority of oceanic islands were first encountered between the mid-eighteenth and late nineteenth centuries by ships from Britain, along with smaller numbers from America, France, and Russia. Most initial encounters arose through exploratory voyages, and seldom involved sustained contact. With only a few exceptions, more lasting engagements arose only after whalers, traders, missionaries, and purposeful colonists began to frequent the Pacific beginning in the last two decades of the eighteenth century; prior to this, there were only six attempts to establish European settlement, and all but one of these failed rapidly. The timing and nature of encounters between the Oceanian and Western worlds varied significantly between islands, providing immense potential for archaeological study.

The practice of historical archaeology is very unevenly distributed throughout Oceania. It is most strongly developed in New Zealand where it began in the 1920s and flourished after the

Oceania: Historical Archaeology, Fig. 1 Oceania, showing places mentioned in text

1960s (Smith 1991), although in recent decades it has been dominated by development-driven consultancy archaeology with its attendant lack of full publication (Smith 2004). In Hawaii, historical archaeology also emerged in the 1960s (Kirch 1985: 303–318) but, with some notable exceptions, has seldom been reported in published sources. Elsewhere activity has been sporadic with clusters of published work from the Solomon Islands, New Caledonia, and Fiji and more limited examples from ten further islands or island groups.

Examples

Archaeologies of Colonial Settlement

In 1595 four Spanish ships set out from Peru with the intention of establishing a colony in the Solomon Islands, discovered in 1568 by their leader Alvaro de Mendana y Neyra. Three of these ships made landfall at Graciosa Bay on Nendo Island, in the Santa Cruz group, establishing a settlement that lasted for less than 2 months before internal tensions, disease, and conflict with locals led to its abandonment. Archaeological investigations in 1970 (Allen 1976) located the settlement which disclosed a defensive ditch, a house floor, and small quantities of Spanish colonial pottery, probably from South or Central America (Gibbs 2011). Near-identical pottery was recovered from two sites at Pamua on San Cristobal Island (Fig. 2) which have been convincingly linked to an historically unrecorded settlement by people from the fourth ship in Mendana's expedition. The quantity and diversity of pottery at these sites suggest that their occupation was of slightly longer duration than on Nendo, but they too were soon abandoned. In this case at least, the impact of colonial settlement on the indigenous people and their environment was minimal.

The only permanent colonial settlement established before the late eighteenth century was founded at Agaña on the island of Guam in 1668. It incorporated both a Jesuit mission and a military presence, and provided a reprovisioning base for Manila-bound galleons on their outward journey from Mexico. Archaeological investigations of the colonial period have been limited, the most significant being excavations on the site of

Oceania: Historical Archaeology, Fig. 2 Ceramic sherds from Pamua and Graciosa, Solomon Islands. (From Gibbs 2011, published with permission of Society for Historical Archaeology)

the Spanish Governor's palace (1744–1898) which was subsequently the seat of American colonial rule then Japanese military government before destruction by bombing in 1944 (Scheutz 2007). This disclosed a ceramic assemblage dominated by oriental, particularly Chinese, wares, with only a handful of sherds attributable to New Spain and none to the Spanish homeland, demonstrating that pottery was not a significant component of the cargoes on the outward journeys of the Manila galleon trade. It also reflects the vibrant East Asian trading network centered on the Philippines since long before Spanish arrival, which was one of the main stimuli for establishment of their colonial presence (Skowronek 2009).

More typical of colonial settlement histories throughout Oceania is Fiji, where European settlement did not begin until the early nineteenth century. Burley's (2003) preliminary analysis of the archaeological record in the town of Levuka charts its emergence as a settlement of European and American beachcombers and their Fijian wives in the 1820s and 1830s, transforming into the major commercial port of call in the island group during the 1860s and its colonial capital in the 1870s, before slowly waning after the 1880s. He highlights the role of imported material goods in maintaining a sense of Europeaness within the settler community but also signifying increasing social differentiation within it.

The most substantial archaeological record of colonial settlement derives from New Zealand, where it has been integrated with the well-established prehistoric record into a long-term culture historic sequence (Smith 2008). The Maori period, covering 500 years of indigenous occupation, is followed by the Pakeha period (1792–1860) during which European immigrants were outnumbered by Maori and constrained in their geographic distribution and the Kiwi period (1860–present) when the immigrant population had numerical, military, political, and economic ascendency. First European contacts took place toward the end of the Maori period, beginning with Dutch exploration in 1642 and resuming again with British and French presence in the two decades from 1769. This was exclusively coastal exploration that left minimal trace in the archaeological record, confined largely to incorporation of the narrow range of metal and glass items initially adopted by indigenous Maori.

The Pakeha period commenced in 1792 with the onset of European settlement. For the first two decades, immigrants were sojourners who spent short periods in residence on New Zealand shores before departing again. The most important group of sojourners was sealers, mostly operating out of Australia, harvesting fur seal skins for Chinese and British markets. Archaeological sites associated with this industry include caves and hut sites that have yielded sparse artifact assemblages (Fig. 3) along with faunal remains dominated by indigenous species, making it difficult to distinguish the archaeological signature of European sojourners from that of contemporary Maori. Permanent European settlement began with the establishment of the first mission station in 1814, followed by another four missions before the end of the 1820s. Archaeological investigation of these earliest permanent settlements has been limited to date, but thorough investigation of a slightly later mission has shown that they operated as small family farming enterprises. European presence was initially confined to the northern and southern ends of New Zealand but expanded geographically in the 1830s with development of the shore-whaling industry. A key feature of the archaeological record of this industry is its diversity, with housing, artifacts, and fauna at some sites almost exclusively European in character while other exhibit distinctive Maori features (Fig. 4). Formal towns were first established in 1840, coincident with the beginnings of British colonial governance of New Zealand, a burgeoning immigrant population and a shift in economic focus from maritime extractive industries toward pastoral farming.

The archaeological record of the first four decades of the Kiwi period is characterized by the emergence of new economic pursuits, evidence of military conflict, and the growth of urbanized settlements. The discovery of gold in 1861 sparked a series of rushes that heightened the pace of immigration and transformed the mid-nineteenth-century economy. This industry was the largest single contributor to the making of

Oceania: Historical Archaeology, Fig. 3 Selected artifacts from occupation by sealers in the Southport caves, Fiordland, New Zealand: *a–c* – glass bottle fragments; *d–f* – pipe fragments of wood (*d*) and clay (*e*, *f*); *g* – gun flint; *h–j* – bone buttons

New Zealand's archaeological landscape in terms of the acreage of land covered by sites. It brought settlement to parts of the interior that had previously seen only transient Maori occupation, and left an archaeological record of both fleeting camps and permanent towns. Among the new migrants were Chinese miners whose ceramics, food containers, opium-smoking paraphernalia, and food preparation methods have all left a distinctive trace in the archaeological record.

Rising immigrant demands for land and heightening Maori resistance to its loss gave rise to a series of wars between various *iwi* (tribes) and changing combinations of British, colonial, and Maori forces. This stimulated two decades of fort building throughout central regions of the North Island and led to massive alienation of land that displaced many Maori communities and disrupted their economic activities. Archaeological investigations have demonstrated innovations in both the technology and strategy of warfare by both colonial and indigenous forces. The urban settlements that developed in the latter half of the nineteenth century have been the main focus of recent archaeological investigations of colonial settlement in New Zealand, but as yet are poorly published.

Archaeologies of Indigenous Cultural Transformation

While many earlier archaeological studies of prehistoric societies in Oceania ended at the point of European arrival, it has become increasingly common for them to explore the ways in which these societies encountered the modern world. These disclose considerable diversity in trajectories of change while at the same time highlighting indigenous agency in these processes. On New Georgia, Solomon Islands, Roviana head-hunting chiefdoms had little direct contact with the outside world until the mid-nineteenth century when trade with Europeans was commenced on terms strongly controlled by Rovianans. Archaeologically, there is little evidence of externally influenced cultural change beyond the appearance of a select range of European-manufactured items

Oceania: Historical Archaeology, Fig. 4 House from Te Hoe whaling station, Mahia Peninsula, New Zealand. The shape and dimensions of the house, its shallow porch, and scoop hearths are typically of pre-European Maori dwellings, while the vertical wooden slab construction and stone chimney are features common in houses of European whalers

on ancestor shrines (Fig. 5), but even these were incorporated into indigenous constructions of personhood (Walter et al. 2004).

While some earlier studies of culture contact in New Zealand posited rapid, widespread, and cataclysmic changes in Maori culture consequent upon European arrival, recent investigations have identified regional variations in the timing and nature of cultural borrowings and demonstrated the persistence of traditional cultural forms. Unsurprisingly the earliest adoptions are at the northern and southern ends of the country, which saw initial sustained European contact, while it was almost a century before European artifacts were common in Maori archaeological contexts from more remote localities (Coutts 1969; Phillips 2000). Irrespective of timing, there is clear evidence of selectivity in Maori adoptions of imported artifacts, plants, and animals.

Phillips' (2000) detailed study covering four centuries of pre- and post-contact Maori settlement in the Hauraki region shows that there were significant changes in settlement pattern, economy, and technology during the first four decades of the nineteenth century but that these were driven almost entirely by intertribal warfare. Although European muskets were utilized, this was essentially traditional warfare conducted for traditional reasons and similar to events that had taken place in earlier times. She characterizes this period as "a dynamic one in which Maori

Oceania: Historical Archaeology, Fig. 5 Historic period artifacts from ancestor shrine platforms, Nusa Roviana, Solomon Islands: *a* –fragment of Tridacna shell back plate for *kapkap* forehead ornament. A circular lattice of tortoise shell would sit over this in a complete specimen; *b* – transfer printed plate ground and drilled for back plate of *kapkap* ornament; *c*, *d* – hammer mechanisms from double barrel percussion cap shotgun; *e* – iron axe head, used as tomahawk. (Courtesy of Tim Thomas, University of Otago)

responses were principally to other Maori. European goods were used to Maori ends" (Phillips 2000: 168). In the 1840s–1850s, Hauraki Maori encouraged European trade in order to increase their access to imported goods which, along with the influence of missionaries, brought greater changes. However, depopulation through epidemic diseases and, later, alienation of land were equally important factors in transformation of the indigenous world.

In Hawaii, Kirch and Sahlin's (1992) study of the Anahulu Valley on O'ahu provides perhaps the most comprehensive archaeological and ethnohistorical analysis of change within an oceanic community as it emerged into the modern world. The initial drivers of changes in settlement pattern, economy, and political organization were indigenous. Following conquest of O'ahu in 1804 during unification of the Hawaiian islands by Kamehameha I, the Anahulu valley, previously only sparsely used, became a well-populated center of agricultural intensification directed toward supplying tribute to the chiefs. At the same time, Hawaii was visited regularly by fur traders, and merchants focused on acquiring sandalwood. Interactions with these visitors were largely controlled by the chiefly class, limiting their impact on the wider community. The archaeological record from Anahulu shows that household clusters established during the first three decades of the nineteenth century conformed to the traditional pattern of a series of functionally specialized structures; with only a limited range and quantity of imported material items, many reworked for traditional purposes.

After 1830 the burgeoning Pacific whaling fleet began to frequent Hawaii, missionary activity expanded, and sugar cane plantations and cattle and sheep ranches were established, expanding connections with the wider world and increasing the pace of indigenous cultural change. Several studies have noted that while some cultural items, such as clothing, changed rapidly, others such as stone adzes remained in use for about a century after contact, indicating complexity in the processes of change (Bayman 2009).

Archaeologies of the Middle Ground

Several recent studies have examined the emergence of communities or social identities that are

neither purely indigenous nor nonindigenous. For example, the Sealers Bay community (1825–1850) on Codfish Island/Whenua Hou, New Zealand, was made up of Maori women, their partners from a diverse range of nations, and their offspring. These hybrid origins are reflected today in its legally sanctioned dual nomenclature, and apparent also in the archaeological record which shows traditional Maori earth ovens alongside European-style housing, and a material culture inventory (Fig. 6) drawn from New Zealand, Australia, and elsewhere in the Western world (Smith 2008).

Bayman (2010) has examined two individuals who played important roles in early cultural exchanges in Hawaii: John Young, a British-born sailor left behind by his ship in 1790 who lived there till his death in 1835, and Kauikeaouli who ruled as King Kamehameha III from 1824 to 1854. Young became an advisor to Kamehameha I during his unification of the kingdom, served from 1802 to 1812 as his governor of the island of Hawaii, and twice married indigenous women. Archaeological investigation of his residence disclosed a combination of Western-style and traditional Hawaiian structures and a similar

Oceania: Historical Archaeology, Fig. 6 Selected artifacts from early-nineteenth-century settlement at Sealers Bay, Codfish Island/Whenua Hou, New Zealand.: *a* – bone fishhook point; *b* – obsidian flake; *c* – chalcedony flake; *d* – fragment from argillite adze; *e–g* – bone buttons; *h* – brass watch hand; *i* – rim sherd of coarse earthenware; *j* – rim sherds of shell-edged whiteware; *k* – clay pipe manufactured by William White Glasgow; *l* – clay pipe manufactured by Joseph Elliot, Sydney

combination of artifacts. Kauikeaouli also combined Hawaiian and non-Hawaiian elements in his residences, and the artifact assemblage from one of these included numerous British, Chinese, and Japanese ceramics which, in contrast to those in sites of commoners, had not been reworked for traditional purposes. Bayman uses these two figures to emphasize the importance of exchange in the construction of the hybrid social identities during early contact in oceanic societies.

In New Caledonia, where the beginnings of historical archaeology are coinciding with the transition to independence after more than a century and a half of French colonial rule, archaeology is informing and enhancing Kanak (indigenous), Caldoche (locally born immigrant), and emerging collective identities. Excavations at penal colony sites have revealed Kanak presence in the convict administration and emphasized convict influence in Kanak clans. Kanak, Caldoche, Asian, and Polynesian school children participating in an ongoing program of excavations perceive the diverse remains they encounter as "just 'one'; the story of their nation under construction" (Sand et al. 2006: 158).

Future Directions

The vast majority of islands in Oceania are completely unexplored by historical archaeologists. Where work has been undertaken, it has disclosed both significant differences and shared themes in trajectories of change as Oceania engaged with the modern world and has highlighted the importance of this "sea of islands" as a laboratory for comparative studies of cultural change. New investigations commencing on missionization in Vanuatu will provide the first evidence of the impact of this process beyond New Zealand and Hawaii. Among other avenues ripe for exploration are comparative studies of the nineteenth-century beachcomber settlements that emerged in many of the ports frequented by trading and whaling ships, and the cultural influences of the numerous groups of indentured laborers who were transported within and into Oceania.

Ogundiran, Akinwumi

Kola Adekola
Department of Archaeology and Anthropology, University of Ibadan, Ibadan, Nigeria

Prolific writer, Professor Akinwumi Ogundiran is from Ibadan, southwestern Nigeria. Ogundiran who has been the chair of the Department of Africana Studies, University of North Carolina, at Charlotte since 2008 had his first degree, a Bachelor of Arts in Archaeology, from the Obafemi Awolowo University, Ile-Ife, Nigeria, in 1988. He bagged a first class honors, a feat that fetched him the Ajayi Fabunmi prize for the best graduating student in archaeology that year at the institution.

He had his master's at the Department of Archaeology and Anthropology, University of Ibadan, in 1991 and completed a doctoral degree program in Studies in African Archaeology at Boston University in the year 2000. Before securing his doctoral degree, Akin Ogundiran briefly worked as a graduate assistant at the Bendel (now Edo) State University, Ekpoma, and as assistant lecturer at the Delta State University and the University of Benin, all in Nigeria.

Major Accomplishments

Akin Ogundiran is a transdisciplinary scholar of Africana Studies. He privilege archaeological anthropology, material science, and historical methods for investigating the multi-scalar networks that framed community and household lives as well as cultural formation in spaces of social complexity. The geographies of his research interest are Africa and the African Diaspora with emphasis on the Yoruba world, especially from 800 A.D. to the present.

Ogundiran has contributed immensely to archaeology through his extensive research on the archaeology of Yorubaland, 1200–1900, and the African Diaspora. For example, the article titled "Material Life and Domestic Economy in a Frontier of the Oyo Empire During the Mid-Atlantic Age" published in the *International Journal of Historical Studies* in 2009 (Ogundiran 2009) addresses how the domestic economy of a hinterland Atlantic African community responded to the commercial revolutions in the Atlantic world. Between 1997 and 2000, he directed the Eka Osun project which focused on historical landscape, social memory, and regional interactions in Ilare District, Nigeria (1200–1900 CE). The result is a series of journal articles and a monograph titled "Archaeology and History in Ilare District (Central Yorubaland, Nigeria) 1200–1900" (Ogundiran 2002).

His recent programs have focused on the emergent qualities of social complexity, sacred groves and landscape studies, material experiences of ritual, and cultural political economies of empire formation of the early modern period. Professor Akinwumi Ogundiran has created novel ways for interpreting and conceptualizing material culture in the cultural history and archaeology of West Africa. For instance, in "The Making of an Internal Frontier Settlement: Archaeology and Historical Process in

Osun Grove (Nigeria), Seventeenth to Eighteenth Centuries" published in *African Archaeological Review* in 2014, Ogundiran used different data sets including the spatial layout of the site, the archaeological depositional sequence, diverse artifact categories, and oral historical sources to engage Igor Kopytoff's conceptualization of the frontier as a conservative space that relied on innovations from the metropolis.

Ogundiran is the editor of *Pre-colonial Nigeria* (Ogundiran 2005) and co-editor with Toyin Falola of *Archaeology in Atlantic Africa and the African Diaspora* (Ogundiran and Falola 2007), with Cameron Munroe of *Power and Landscape in Atlantic West Africa* (Monroe and Ogundiran 2012), and with Paula Saunders of *Materialities of Rituals of the Black Atlantic* (Ogundiran and Saunders 2014).

The scholar is a member of several editorial boards of journals around the world particularly those with special interest on African Archaeology; among these are the *African Archaeological Review*, *Journal of African Diaspora Archaeology and Heritage*, and *Azania*. He is also on the editorial board of *Journal of African Military History*, *International Journal of Philosophy and Public Affairs* as well as *African Histories and Modernities*. He is a founding co-editor of *Yoruba Studies Review.*

In the same vein, Akin Ogundiran's research has enjoyed funding from several notable funding bodies with the latest being awarded the Alfred Yip Fellow, Magdalene College, University of Cambridge in 2017. Other organizations that have identified his research include Wenner-Gren Foundation for Anthropological Research, National Endowment for the Humanities and Dumbarton Oaks, and Boston University Humanities Foundation.

The list of his publication outlets is as wide as his awards as a renowned archaeologist. His awards include the University of Texas at Austin Africanist Award for Research Excellence and the UNC Charlotte Center for Academic Excellence Teaching Award in 2011. In 2007, the United States House of Representatives gave him a special recognition certificate for Excellence in Community Service.

Okladnikov, Alexey P.

Vyacheslav I. Molodin
Institute of Archaeology and Ethnography, Siberian Branch of the Russian Academy of Sciences, Novosibirsk, Russia

Basic Biographical Information

Alexey Pavlovich Okladnikov (1908–1981) was a Soviet archaeologist and historian who specialized in human prehistory, archaeology, and ethnography of Siberia, the Russian Far East, and Northern, Central, and Eastern Asia. He was born in Konstantinovshchina village of the Irkutsk Governorate in Siberia and was educated at the Irkutsk Pedagogical College before going to the Irkutsk State Pedagogical Institute to become one of the prominent Soviet historians who founded the Siberian school of archaeology.

In 1927 he joined the Irkutsk Museum as Head of Division, remaining there until 1934, when he left to study in the State Academy of the History of Material Culture in Leningrad as a postgraduate student. He continued to work there as a senior researcher until 1949. In 1947 he received his doctorate degree. In 1949–1950 he was the deputy director and head of the Leningrad Division of the Institute of the History of Material Culture. In 1951–1961 he was the head of the Department of Paleolithic in the Leningrad Division of the Institute of Archaeology. He joined the Siberian Branch of the USSR Academy of Sciences in 1961, working as head of the division of Human Research and Deputy Director of the Economics Institute until 1966. In 1962 he became professor

and head of the Department of History at the Novosibirsk State University.

In 1964 he became a corresponding member of the USSR Academy of Sciences. In 1965–1981, A. P. Okladnikov was a member of the Presidium of the Siberian Branch of the USSR Academy of Sciences. He was a founder and director of the Institute of History, Philology and Philosophy of the Siberian Branch of the USSR Academy of Sciences (1966–1981). From 1968 he was the executive editor of the journal *Izvestiya SO AN SSSR. Seriya obshchestvennykh nauk* (*Proceedings of Siberian Branch of the USSR Academy of Sciences. Series of Social Sciences)*. He was elected as a full member of the USSR Academy of Sciences (1968), a Corresponding Fellow of British Academy (1973), a foreign member of Mongolian Academy of Sciences (1974), a foreign member of Hungarian Academy of Sciences (1976), and an honorable doctor of sciences in the University of Poznań, Poland (1978). He was also a co-chairperson of the Soviet-Hungarian Committee of Historians.

A. P. Okladnikov was awarded with state prizes and the highest decorations of the USSR and foreign countries as well. His memory is perpetuated with a memorial plaque mounted on the building of the Institute of Archaeology and Ethnography SB RAS in Novosibirsk, and one of the caves in the Altai Mountains and an auditorium at the Novosibirsk State University were named after him. The Okladnikov prize was introduced for young scientists, and the scholarship in his name was established for students of the Novosibirsk State University.

Major Accomplishments

A. P. Okladnikov substantially contributed to the interpretation of human origins, as well as the early peopling of Northern Asia and America. He was the first to discover numerous sites dating back to the Paleolithic, Neolithic, and Bronze Ages in Siberia and the Russian Far East, including the first Neanderthal remains ever found in the territory of the USSR (1938, Teshik-Tash Cave in Uzbekistan). He discovered and explored the main areas of petroglyphs found to vary in styles and ages, dating from the Paleolithic to the medieval times. He was recognized as the leading authority on the prehistoric rock art. He directed the Soviet-Mongolian archaeological expedition (1960) and the Soviet-American Siberian Expedition in Alaska (1975). *The History of Siberia* was the first summary edition on the history of the eastern regions of Russia, published in five volumes under his editorial guidance.

Oldowan Industrial Complex

Kathleen Kuman
School of Geography, Archaeology and Environmental Studies, University of the Witwatersrand, Johannesburg, South Africa

Introduction

The earliest traces of hominid cultural behavior are 149 stone tools dating to 3.3 Ma in Kenya at a site called Lomekwi 3 (Harmand et al. 2015). Large, heavy cobbles and blocks of lava were

used for cores, with 86% showing they had been worked between a hammerstone and a rock anvil (the bipolar technique) or struck against an anvil resting on the ground (the passive hammer technique). The flaking was poorly controlled, as some cores have repeated impact marks far from the edge and scars for removals often end in a step or a hinge. Because this small assemblage is characterized by percussive actions rather than skillful flaking, it has been called the Lomekwian industry and is considered to represent the dawn of lithic technology. For many years prior to this exciting discovery, researchers believed that rocks used in percussive activities must be the way in which early hominids realized that stone could be flaked to produce sharp-edged flakes – particularly because some modern African apes and even some South American monkeys use stone to break open nuts. Even earlier than 3.3 Ma, however, tools in perishable materials were certainly used and modified by ancestral hominids, because there are many such examples used by nonhuman primates. For example, chimpanzees use a variety of items as tools: leaves as sponges for water extraction and for hygiene, twigs and stems to extract termites from their mounds, hammers and anvils in both stone and wood to break open nuts, sticks to extract honey from beehives, and, most dramatically, sticks sharpened with their teeth to kill bush babies in their sleeping holes in trees. There are also recorded examples of proper toolkits that involve sticks of different thickness and strength taken to a site for extracting food, such as termites. Chimps are observed to deepen the hole in the crown of oil palm trees and use a frond as a pestle to pound and mash up the apical bud of the tree for food. Orangutans also are observed using sticks to extract fruit from its casing, and gorillas have been seen to use a stick to probe the depth of water (for a review, see Haslam et al. (2009) in Further Reading).

Some 700,000 years following the Lomekwian, the Oldowan industrial complex begins, with artifacts consisting of simple cores and flakes. The earliest Oldowan site is Ledi-Geraru in Ethiopia, dating to between 2.61 and 2.58 Ma (Braun et al. 2019). This is followed by three sites at Gona, also in Ethiopia, dating to 2.58 and 2.55 Ma (Semaw et al. 1997; Semaw 2000; Semaw et al. 2009). The knowledge of how to select appropriate raw materials and how to flake cores effectively to produce sharp-edged flakes is evident at all of these earliest Oldowan sites. We know enough today about Oldowan technology to engage in substantive debates about flaking skills, as there are more than 30 sites where the Oldowan is well documented in Africa. The overwhelming majority is found in East Africa where many assemblages, large and small, are known in Ethiopia, Kenya, and Tanzania (Gallotti 2018; Toth and Schick 2018). Four Oldowan sites are known in South Africa, with numbers of artifacts ranging from two or three at Kromdraai B to 30 at Wonderwerk Cave (Chazan et al. 2008), to over 1800 at Swartkrans (Kuman et al. 2018), and to 3500 at Sterkfontein (Kuman and Field 2009). Oldowan sites are also known in Algeria, at Ain Hanech, El-Kherba, and Ain Boucherit (Sahnouni et al. 2002, 2018). In the central African DRC, one assemblage in disturbed context is reported. Thus despite the limited occurrence of sites outside of East Africa due to constraints of geological preservation or little research, the distribution of Oldowan assemblages shows that this earliest technology was a widespread African phenomenon.

Definition

The Oldowan is defined as an early form of lithic technology that consists mainly of flaked cobbles (called cores) and the flakes struck from these cores, which were used largely in various cutting tasks suitable to their sharp edges. Glynn Isaac, a leading East African archaeologist, accurately assessed Oldowan technology as a "least effort solution" to the subsistence needs of early hominids. Most archaeologists believe that Oldowan flakes were used initially to cut meat, probably from carcasses scavenged or wrested from carnivore kills on the landscape, but soon their use was extended to other subsistence activities. This cultural tradition first appeared in Africa ca. 2.6 Ma and persisted until 1.7 Ma as a variable but simple set of regional developments grouped together as an Oldowan industrial complex. Just over 1.7 Ma,

these basic core and flake tool kits were supplemented by the first purposefully shaped heavy-duty tools in the form of hand axes and cleavers, ushering in the Early Acheulean complex. As a simple core and flake technology, the Oldowan is also referred to as a Mode I industry. The earliest well-dated occurrences in good context for such simple tools beyond Africa are at Shangchen in China ca. 2.1 Ma, at 1.85 Ma at Dmanisi, Georgia, and from ca. 1.7 in the Nihewan basin in China (see Zhu et al. 2018 for references). Beyond Africa, however, the industries are referred to as Mode I, to distinguish them from the African Oldowan, where the technology originated.

The Oldowan tradition is most often described and compared across assemblages by its core types, which Leakey (1971) described as heavy-duty tool types in her seminal work on the subject. Leakey terms these heavy-duty types as follows: choppers, cobbles flaked along the side or an extended edge, either unifacially or bifacially; discoids, cobbles flaked in a radial direction, usually on both faces; polyhedrons, cobbles flaked in random directions, obtaining a multifaceted shape; heavy-duty scrapers or core scrapers, cobbles flaked downward from a flat surface; and spheroids and sub-spheroids, polyhedrally flaked cobbles that have been battered down through use to a more spheroidal shape. Leakey considered the sharp edges where flaking platforms met to be the functional parts of the tool. She also categorized light-duty tools, consisting mainly of modified flakes, scaled pieces (outils écaillés), and occasional awls and burins. The latter two types are, however, much debated. Many archaeologists continue to use a modified version of Leakey's classification because it has good descriptive value, but most would also recognize that her heavy-duty types are mainly cores. Many thus prefer to use the terms of chopper cores, discoidal cores, polyhedral (or multifacial) cores, and single platform cores (as opposed to core scrapers, unless some use-wear justifies calling the piece a scraper). While any core type can also be used as a tool, it is important to have some evidence of use-wear on the functioning edge of the piece to call it a core tool. Spheroids have been variously discussed as tools used to pound and process food or as cobbles and cores used persistently as hammerstones, which eventually produce a more spheroidal shape.

Freehand, hard hammer percussion is the most common method used in the Oldowan (Figs. 1 and 2), but bipolar flaking is also present in some assemblages, particularly those with quartz (or Naibor Soit quartzite at Olduvai, which is often called quartz). In this technique, the pebble or cobble to be flaked is rested on a stone anvil and struck from above with a hammerstone. In contrast with the Lomekwian, bipolar flaking is not usually common in Oldowan assemblages, although exceptions occur. For example, bipolar flaking is a major component of the Swartkrans Oldowan (ca. 2 Ma) and is even used on chert and fine quartzites (Fig. 3;

Oldowan Industrial Complex, Fig. 1 Quartzite cores from the Oldowan at Sterkfontein

Oldowan Industrial Complex, Fig. 2 Quartz cores from the Oldowan at Sterkfontein

Oldowan Industrial Complex, Fig. 3 Artifacts from the Swartkrans Oldowan. *Left*: drawings of bipolar cores, with a and e in quartz and b, c, and d in quartzite, all record bipolar working except for e, which has a mix of bipolar and freehand removals. *Right*: a is a subspheroid made in quartz; b is a quartzite single platform core with five bipolar removals; c is a simple bipolar core in quartzite where a single blow has fragmented the piece (see portions to either side of the central ridge left on the core)

Kuman et al. 2018). The throwing of cobbles to initiate fracture is another technique sometimes discussed, but its characteristics can be difficult to recognize as they vary with the shape and properties of the rock.

Historical Background

The term "Oldowan" derives from Oldoway, an early name for Olduvai Gorge in Tanzania, where Louis Leakey found such tools and compared

them with other occurrences in East Africa. M. D. Leakey (1971) provided the first well-defined and fully illustrated description of the industry in her monograph on the early archaeology of Olduvai Gorge, where the relevant deposits date from 1.9 to 1.8 Ma. It was common in her day to consider that the movements of different hominid groups or hominid species were responsible for sudden changes in industrial traditions, such as the first appearance of the Early Acheulean ca. 1.6–1.4 Ma in the Olduvai sequence. Such changes in the archaeological record may appear to be sudden for geologic reasons, as no early sequence is continuous or they may indeed be sudden. Evolutionary changes in anatomy or behavior can be punctuated in nature, particularly if adaptations or innovations arise in small, localized populations that may not preserve in the fossil or archaeological records. At Gona, Ethiopia, Semaw et al. (2009) document what does in fact appear to be the sudden appearance of Early Acheulean, which they also note for other sites in East Africa. However, working in the 1970s, M. D. Leakey took a combined approach that argued for both the sudden appearance of the Early Acheulean and continuity of the Oldowan tradition. She described this continuity by grouping the Olduvai sites in a series of stages: Oldowan, followed by Developed Oldowan A at 1.7–1.6 Ma, Developed Oldowan B ca 1.5–1.4 Ma, and Developed Oldowan C persisting through much younger beds in the Olduvai sequence. Hand axes (or bifaces) were said to appear in Developed Oldowan B, but they were usually smaller than Early Acheulean examples, and as a type, they comprised less than 40% of the "core tool types" as defined by Leakey. Subsequently, some archaeologists continued to use the Developed Oldowan as an industry which contrasts with the Early Acheulean, but the A-B-C designations were avoided. Today, few researchers use the term, as the distinctions have been ascribed to differences in raw materials and in intensity of re-sharpening of the bifaces (see Semaw et al. 2009) for a comprehensive review and assessment). The result is that the Oldowan tradition is widely viewed as a distinct industry that arose by 2.6 Ma and persisted until 1.7 Ma. Semaw et al. (2009) would place the Developed Oldowan A with the Oldowan complex and the B and C variants with the Acheulean, which is also the majority opinion of other researchers.

The work of Toth (1985) was influential in shifting the historic focus on Oldowan typology and cores as tools to a more dynamic understanding of the relationship between artifacts and the raw materials on which they were made. In an experimental approach, he demonstrated how the shapes and sizes of the flaked cobbles influenced the resulting core types. He thus turned the focus from core tools to cores, arguing that the central goal of the Oldowan was to obtain sharp-edged flakes for multiple tasks but initially for the cutting of meat from animal carcasses.

Another important methodology for study of Early Pleistocene lithic assemblages was developed by Schick (1987). Both Schick and Toth worked with Glynn Isaac, whose many students were encouraged to develop projects (particularly at Koobi Fora, Kenya) that would tease out the behavioral information from the natural geologic and biological modifications to sites and their lithic and faunal assemblages. Schick's work focused on the formation and transformation of archaeological sites by natural forces, particularly in shallow water contexts affected by flooding, as most East African sites were associated with low-energy riverine deposits and lakeshore sedimentation processes. She concluded that sites exist in a continuum of contexts, from primary or pristine, largely undisturbed sites, to secondary, disturbed contexts, as well as a range of contexts intermediate between these two extremes. The movement of water across a site has the power to winnow out the smaller material, and at higher velocities it also will orientate the larger pieces in specific directions that respond to current direction and strength. Working with experimentally created assemblages, Schick also demonstrated that an undisturbed assemblage flaked on-site should consist of 60–85% of small flaking debris (pieces under 20 mm in length). Some experimental assemblages, such as those made in brittle materials like quartz, even show much higher percentages of small flaking debris (Kuman and Field 2009; see Fig. 4).

Oldowan Industrial Complex, Fig. 4 Experimental flaking of vein quartz, showing the large majority of small flaking debris in an undisturbed, complete assemblage

In these earlier years, Isaac and a number of his other students also explored the behavioral implications of sites with large numbers of bones and stones, which in the 1970s had been considered a form of home base to which hominids repeatedly returned. Over the next couple of decades, various explanations for these large sites took shape, aiming to test this "modern human" interpretation of early hominid behavior (see Plummer 2004 for a review). The formation of large sites was modeled and debated by various researchers as follows: central place foraging sites; sites that were repeatedly reoccupied by routed foraging of fixed resources; caches of lithic material actively moved to strategic locations or, alternatively, more passively accumulated lithic and bone debris forming over time at favored locations; activity locations such as kill sites; and venues where hominids gathered for safety against carnivores or took refuge to consume game that was scavenged from carnivore kills. The study of bone fracture patterns, along with cut marks indicative of scavenged or butchered game and percussion marks from the breaking open of bones for marrow, has become a highly developed method of analysis in interpreting these models and early hominid behavior in general.

Key Issues/Current Debates

The Timing of Access to Animal Carcasses

The behavioral models discussed above were hotly debated in earlier years, and many faunal analysts today continue to explore questions raised by these models, e.g., were hominids limited to scavenging scraps of animal protein from carnivore kills (i.e., late access) or did they have early access to these carcasses, obtaining the meatier portions. Researchers thus still debate the exact nature of the interaction hominids had with the associated faunas, but this is largely a research focus for the East African sites. In South Africa, only one hominid site with Early Pleistocene tools bears significant numbers of cut and percussion marks, left by the processing of carcasses by hominids, and in this case interpreted as early access (Pickering and Brain 2010). The modes of accumulation for South African faunal assemblages instead are dominated by natural and biological agents, such as carnivores, natural deathtraps, and slope wash or collapse around cave entrances. Being in secondary contexts, the lithic assemblages from these hominid sites require thorough investigation of the site formation processes affecting their accumulation before behavior (other than technological) can be interpreted. At Sterkfontein, the fauna associated with Oldowan artifacts is largely a deathtrap accumulation, with some contribution from slope wash.

Tethering to Raw Material Sources

One of the traits commonly discussed for the Oldowan is the tethering of these sites to raw material sources. While there are some exceptions, there is indeed a fairly strong pattern of Oldowan sites being more "tethered" to raw

materials than are Acheulean sites. However, Oldowan-bearing deposits are limited in number, and perhaps "tethering" is not the best term. It might be more accurate to say that stone tools are more "archaeologically visible" close to significant sources of raw material. Hominids undoubtedly transported stones and tools across the landscape to food resources, but it was primarily close to gravels and rock outcrops that hominid activities preserved best as archaeological sites. Nowhere is this clearer than in South Africa's Cradle of Humankind in Gauteng Province. This world heritage region preserves at least 14 sites with fauna and many with hominids, but during the Early Pleistocene, only the sites close to the major gravels of the Blaaubank River have substantial numbers of stone tools. At Sterkfontein and Swartkrans, both sites that are quite close to gravels, the artifacts number in the thousands, from Oldowan to Acheulean and even Middle Stone Age. Kromdraai, Coopers, and Goldsmith's sites are also relatively close to the Blaaubank gravels, but at these sites, Early Pleistocene artifacts are found in smaller numbers, perhaps because they were not so geographically favored as activity sites. And sites at considerable distance from raw material sources, namely, Gladysvale and Drimolen, have yielded only a handful of artifacts between them, while others have none at all.

Our interpretation of hominid behavior from lithic assemblages in the Oldowan is undoubtedly influenced by the methods of analysis we use. Braun and Harris (2003) have suggested a means of analyzing whole flakes in early assemblages that goes beyond simple linear measurements, which are the focus of most studies. They apply a "flake utility" index calculated from the length of a flake edge (or perimeter) in relation to the mass (or overall volume) of the piece. In particular, they compare Kenyan assemblages from Koobi Fora from the KBS/Oldowan industry (1.89–1.65 Ma) with Developed Oldowan assemblages from the Okote Member (1.65–1.30 Ma). Their goal is to use assemblages with good palaeoenvironmental and geomorphological data to address early hominid behavior in ecological terms, which they argue is a necessary prerequisite before considering hominid abilities and change through time. They conclude that the Oldowan hominids at Koobi Fora contrasted with later hominids, who knapped in a way that maximized a flake's cutting edge in relation to a given volume of raw material. By their calculations, the Developed Oldowan hominids produced at least double the number of flakes per core volume as did the KBS hominids, which would have conserved stone and allowed them to range further from raw material sources. The method is promising, but due to the small database that exists for Oldowan sites with good environmental reconstructions, it can be complicated to interpret exactly how these observations may relate to ecological and geographic factors vs. change through time.

Landscape Archaeology

At some East African site complexes, contemporary Oldowan sites occur over distances of one or more kilometers (e.g., Olduvai and Peninj in Tanzania and Koobi Fora in Kenya). Volcanic deposits provide the means of dating and correlating such deposits in both space and time, making study of hominid behavior across a portion of the landscape possible. At Olduvai, artifacts excavated from dated sites can sometimes be traced to specific raw material outcrops, which allow us to reconstruct the larger movements of hominids on the landscape. The South African early archaeological record is preserved in very different contexts. The three sites in Gauteng's Cradle of Humankind which have deposits with Oldowan-aged tools are Sterkfontein, Swartkrans, and Kromdraai B. All are underground caverns in dolomitic limestone, where material has been redeposited from occupations on the surface. In the past, researchers relied on fauna to provide relative ages. Improvements in chronology today have been made with uranium-lead dating of karst cave flowstones and cosmogenic nuclide burial dating of quartz sediments or quartz contained in lithic manuports (e.g., Granger et al. 2015). Electron spin resonance dating has also been attempted, but the geologic contexts of these sites make it a more problematic and controversial method. Even the dating of deposits with

uranium-lead must be done with great care, as many flowstones are postdepositional in time, filling in voids created by subsidence of hardened breccias or capping older deposits hundreds of thousands of years later. For the cosmogenic burial method, accuracy depends on the absence of reworking of the samples within a cave system. The recent report of Oldowan period tools at Wonderwerk Cave in the Northern Cape is in a different karst context (Chazan et al. 2008). This cave records a long sequence of occupations from the Earlier to the Later Stone Age. The lowest unit is ca 1.85 Ma and contains 2 cores and 28 small flakes. This is the only Oldowan assemblage in Africa yet found in a habitable cave context. However, the assemblage is small, which differs with later cave occupations that begin only in the Middle Pleistocene, and Wonderwerk may not have been an Oldowan occupation so much as a comfortable place to shelter from the elements.

Knapping Abilities

In recent years, the Lokalalei 2C site in Kenya (western Lake Turkana) has become almost as iconic as the important sites of Olduvai. At 2.34 Ma, this open-air site has such a well-preserved assemblage that Delagnes and Roche (2005) have been able to refit many sets of artifacts and reconstruct the selection of cobbles, along with the flaking patterns and decisions made by the hominids. Describing the "chaine operatoire" (or operational chain of actions), the authors conclude that these hominids had a good mastery of flaking skills, even planning some more complex technical actions when flaking the best shaped cobbles. They first selected angular cobbles and fragments with good edge angles for flaking, and then they exploited a large flat face as the best flaking surface. Refits showed that an average of 18 flakes was struck per core; however, in one instance, a minimum of 51 flakes were knapped, and in another, more than 73 flakes were obtained from a cobble that yielded several large fragments cycled into cores. Hammerstone impact marks show a skillful level of control (also typical of other Oldowan assemblages – Gallotti 2018). While such intelligent flaking was applied to better raw materials, poorer-quality rocks were flaked in a simpler manner. At the same time, however, the Lokalalei 2C hominids did not attempt to work rocks with less amenable shapes, which later hominids were able to master by creating the correct angles, and when the good flaking angles were lost on a core, they did not attempt to adjust them. The authors conclude that the Lokalalei 2C hominids were thus limited in their mastery of flaking, but they also state that the raw material source was less than 50 m from the site. This abundance of raw material complicates behavioral interpretation, as the hominids did not need to conserve their raw materials by correcting problems on the cores. Many more Oldowan sites and assemblages are undoubtedly needed to address such debates as skill vs. economical needs or even variability due to simple motivational differences in hominids. All of these factors influence the interpretation of archaeological sites in terms of early cultural behavior.

At a somewhat older site at Hadar, Ethiopia, Hovers (2009) has argued that hominids in fact did have some ability to correct knapping mistakes. As cores were worked to the point that flaking angles became problematic, flakes were at times detached which did not end in a fine-feathered termination but instead broke off with a stepped or hinged distal end. This left the core with a compromised surface for further flaking. Correction occurred when such cores were often rotated, so that a large flake could be struck to remove the problem area.

Even at the oldest sites at Gona, 2.6 Ma, assemblages show a clear understanding of fracture mechanics and a developed ability to make stone tools (Semaw et al. 2009). There are no signs of "incipient" abilities that improve with time, either at Gona or in the Oldowan in general, although some researchers have suggested earlier assemblages show more unifacial (than bifacial or complex) flaking. But although unifacial flaking of cobbles is prominent at some early sites, other methods are also used, and cores with complex, multifacial and bifacial flaking are of equal antiquity. Unifacial flaking seems rather to be influenced by raw material forms and the degree of intensity of flaking. Cores (and not only raw materials) were also transported to the Gona sites

for further flaking, which also is found at Sterkfontein, where many quartzite cores and flakes were brought into the site, in contrast with quartz and chert with size profiles that show they were flaked on-site. Such patterns are not uncommon in the Oldowan.

Raw Material Selectivity

The most commonly reported feature for Oldowan assemblages is the hominids' ability to determine not just the appropriate shapes of cobbles to be flaked but especially the quality of rocks and their flaking properties. Semaw et al. (2009) discuss this selectivity for the 2.6 Ma artifacts from the Gona sites. Here the raw materials consist of a number of igneous rock types. Surveys of available raw materials show that hominids selected rocks that were fine-grained and of better flaking quality, because such rocks produced tools that were sharper and more durable. The same applies to many other East African sites.

The Oldowan industry from Sterkfontein, South Africa, also exemplifies the selection of rock types for specific flaking properties ca 2 Ma (Kuman and Field 2009). Although quartzite is the most common rock type in gravels close to the site and chert is also common, the assemblage is dominated by vein quartz, which is less common, and the focus for tools was on sharp edges for light-duty cutting tasks. Vein quartz is extremely easy to flake (even in cobble shapes that are not ideal) because it is brittle, and as flaking of cobbles progresses, chunks are produced that can be further cycled into cores. The best rock for flaking at Sterkfontein was carried into the site from the river terrace a few hundred meters away. Swartkrans lies on the other side of the Blaaubank River to Sterkfontein, and the site seems to have been a little closer to the raw material source. Such differences demonstrate the importance of sampling in Oldowan archaeology. Only more assemblages in differing geographic and environmental contexts can reveal the extent of the variability and potential explanations for such differences.

Was the Oldowan Unchanging?

An important debate for some years has been the nature of the Oldowan as an evolutionary stage in cultural behavior. Semaw et al. (2009) and Stout et al. (2010) have argued that Oldowan technology persisted with little or no change for almost a million years, until the Early Acheulean appeared just over 1.7 Ma. They argue that the skill manifested from the beginning of the Oldowan, until the Developed Oldowan/Early Acheulean, is indicative of a stable, successful adaptation. At 1.7 Ma, environmental reconstruction points to a shift to drier climates, and this change coincides with the end of the period of Oldowan stasis. In contrast, others have argued that there is change exhibited during the Oldowan, with differences between the earliest assemblages (from 2.6 to 2.0 Ma) and the classic Oldowan so well known from Olduvai Gorge (1.9 to 1.7 Ma) (Kibunjia 1994; Delagnes and Roche 2005). Originally some researchers argued for a pre-Oldowan phase prior to 2.0 Ma, which has been replaced more recently by terms such as early vs. late Oldowan. The Lokalalei 2C site was pivotal in this debate as an example of the more skilled side of technological variability, suggestive of population-based differences that drove cultural (and probably also hominid) evolution. In particular, this site is contrasted with Lokalalei 1, where hinged and step-terminated scars on the cores indicate problems with the detachment of good flakes. However, critics argue that this site has problematic raw material, and it is a fact also that Lokalalei 2C shows evidence of both simple and more sophisticated flaking strategies, undoubtedly practiced by the same population. However, Gallotti (2018), in her review of some 27 East African Oldowan sites, argues against the concept of Oldowan stasis. Her reasoning (p. 26) is that, despite the presence of a variety of flaking methods in the earlier sites, some were not used consistently but "only tested," unless one examined such developments at the "inter-site scale."

Ultimately, however, opinions in this debate hinge on how stasis is actually defined, given the variability that is now documented for over 30 Oldowan sites documented across Africa. Should it be defined by the number of reduction strategies used or by the upper limits present in any particular assemblage, even if a strategy is rare? Moreover, technological and typological

differences are affected by many factors, e.g., abundance of (vs. distance from) raw material sources, ecological differences across Oldowan landscapes, specific raw material properties, individual motivation, and random walk variability. It is true that Lokalalei 2C has more retouched pieces than other early Oldowan sites, but this is an unusually well-preserved assemblage. It is also true that some of the classic Oldowan sites at Olduvai are long-term accumulations, which are more likely to preserve a greater variety of modified tool types. Additionally, some researchers have questioned the identification of retouched pieces at some Olduvai sites, which puts the argument even deeper into the realm of debate (de la Torre and Mora 2005).

Who Made the Oldowan?

There are various hominid species present on the African landscape during Oldowan times, 2.6 to 1.7 Ma. In East Africa, these include *Paranthropus aethiopicus* and *Paranthropus boisei*, the early *Homo* species of *H. habilis* and *H. ergaster*, and the *Australopithecus* species of *A. garhi* and certain specimens designated as late-occurring examples of the *Australopithecus* (see Cross-References on *Homo habilis* and Clarke 2012). In South Africa, there are also multiple species existing between 2.6 and 1.7 Ma: *A. africanus*, *A. prometheus*, *A. sediba*, *P. robustus*, *H. habilis*, and *H. ergaster* (see Cross-References noted below), although only *P. robustus* and *H. habilis* are found in association with Oldowan assemblages.

There are many researchers who firmly believe that all hominids were intelligent enough to have made Oldowan tools of one variety or another. While it is impossible to prove that some *Paranthropus* and *Australopithecus* individuals never used any stone in their subsistence behavior, the Oldowan does show a certain developed level of intellectual and manual skill and selectivity of raw materials, which suggests that early *Homo* was the main or possibly the only species able to master this level of tool manufacture. *Paranthropus* was a species highly adapted to tough or hard "fallback foods" that helped it to survive during difficult times. It became extinct ca 1 Ma, which indicates it did not possess the kind of flexible, adaptive behavior we see recorded in the Oldowan. On the other hand, the Lomekwian industry at 3.3 Ma is characterized by a less developed technology. It predates both the Oldowan and the earliest *Homo* fossils and may have been made by *Kenyanthropus platyops*, dated ca. 3.3–3.5 Ma.

Future Directions

Debates regarding Oldowan cognitive abilities and subsistence behavior are alive and well, although they will require many more excavated sites in datable contexts, with good palaeoenvironmental reconstructions, along with in-depth analyses of the lithic assemblages, to reach better consensus. However, there is much we now know about the widespread distribution of the Oldowan tradition in Africa, from North to South, and this situation will only improve with further research.

Olduvai Gorge Archaeological Site

Jackson K. Njau
Department of Geological Sciences and The Stone Age Institute, Indiana University, Bloomington, IN, USA

Introduction

Olduvai Gorge is an exceptionally rich archaeological site, preserving one of the best records of human history spanning nearly 2 Ma. The site has yielded abundant human and animal fossils and stone artifacts preserved in well-dated stratigraphic sequence. The quantity, quality, and geological context of paleontological and archaeological data provide a yardstick for rates of evolutionary changes in human form and stone tool technology. Over four hominin species, including the holotypes for *Paranthropus "Australopithecus" boisei (Zinjanthropus)* and *Homo habilis*, as well as remains of *Homo erectus* and prehistoric *Homo sapiens* have been discovered at the site (Leakey 1971). The hominin record is consistent with the evolution of stone tool technology from the Oldowan to Acheulean, Middle Stone Age, and Later Stone Age industries. The Oldowan industry (characterized by simple core-and-flake stone technology) is the earliest known human technology and was first discovered at Olduvai Gorge. More than 200 vertebrate taxa, including approximately 25 holotype species, have been documented at the site. Fossil and associated paleoenvironmental data establish the composition of the Plio-Pleistocene vertebrate communities in East Africa.

Definition

Olduvai Gorge (approximately 25 km in length and up to 100 m deep deposits) is located in the Ngorongoro Conservation Area, northern Tanzania, which is inscribed by UNESCO's World Heritage Committee as a "Mixed Property" (http://whc.unesco.org/en/list/39) (Fig. 1). The Olduvai sequence, which dates from 2.03 Ma to c. 62,000–17,000 years old, is divided into seven stratigraphic units defined from the oldest to youngest as Beds I–IV, Masek, Ndutu, and Naisiusiu (Fig. 2). Bed I and basal Bed II deposits are the best studied part of the sequence, due to the abundance of Oldowan tools and Plio-Pleistocene faunal remains found there. These older deposits have yielded fossil remains of *Paranthropus "A" boisei, Australopithecus cf. africanus*, and *Homo habilis* (Leakey 1959; Leakey et al. 1964; Clarke 2012), suggesting that three distinct forms of human ancestors lived contemporaneously during the Oldowan time, when the central portion of the Olduvai basin was occupied by a fluctuating saline-alkaline lake (Hay 1976).

Key Issues/Current Debates/Future Directions/Examples

Olduvai provides a rich record for investigating some of the fundamental questions in human evolutionary studies. These include the evolution of early behaviors of Oldowan hominins, the timing and nature of the technological shift from the Oldowan to the Acheulean, and the transition from late *H. erectus* to early *H. sapiens* (Leakey 1971; Rightmire 1983). However, this entry focuses on the origins of hominin foraging and land use behavior with evidence from the Olduvai paleo-basin.

The origins of complex social behaviors and the ecological contexts in which early human behavior evolved is one of the major problems in

Olduvai Gorge Archaeological Site, Fig. 1 A view of Olduvai Gorge as seen today

paleoanthropological research. Scientists depend on a variety of evidence from the archaeological record, which preserves traces of hominin behavior, such as stone artifacts or fossilized bones of wild animals bearing stone tool cut marks or hammerstone percussion marks. Carnivore bite marks are also important, and if detected in the fossil record may indicate the degree of predator or scavenger activity on ancient landscapes. These feeding traces are important in understanding past ecological processes, such as competition, carcass persistence, and survivorship of skeletal material, and are significant in understanding the scale of hominin-carnivore interactions and the role of predation in human evolution.

Since their initial discovery, the dense concentration of crude stone artifacts in association with fossilized bones of large and small vertebrates preserved in thin layers of sediments at Olduvai were speculated to represent "occupational sites" or "living" sites, where early hominins manufactured and/or discarded tools, processed carcasses, and consumed meat on a scale unknown among modern nonhuman primates (Leakey 1959, 1971). Living sites were viewed as favorable points on a landscape or "home bases" at which breeding groups of hominins conducted social and maintenance activities such as hunting, food sharing, and division of labor (Isaac 1978).

This generalized idea, adopted from 1960s ethnographic observations of hunter-gatherers and championed by Glynn Isaac in the 1970s, conceptualizes the evolution of early hominins as a complex interaction of social and biological adaptations. The premise of this hypothesis is that tool making, tool use, and meat eating played major roles in promoting brain development and increased social complexity. Therefore, hominin carnivory behavior, increasing dependence on stone tools, and cooperation between and within the sexes led to the advent of organized hunting, the family unit, and the division of labor, with all social and subsistence activities being centered spatially around a home base (Isaac 1978). The occurrences at Olduvai of stone tools together with broken-up animal bones, some bearing butchery marks, therefore, suggested that complex social behaviors had already evolved in Africa by 2 Ma ago (Leakey 1959; Isaac 1978).

Numerous archaeological sites recovered from Beds I and II by the Leakeys were widely accepted as home bases. These include DK (levels 1–3), FLK NN (level 3), FLK (*Zinjanthropus* level or level 22),

Olduvai Gorge Archaeological Site, Fig. 2 The Olduvai stratigraphy. (Modified from Hay 1976)

FLK N (levels 1–2), HWK E (levels 1–2), BK, and MNK. Since the early 1980s, archaeologists focused on the analysis of lithics and fossil bones of these assemblages, but FLK *Zinjanthropus* has received more attention than any other Oldowan assemblage because it is the largest and best preserved tool-marked bone sample.

The early view that these sites represented home bases of hominin occupation was challenged by Binford (1981), who argued that the stone artifacts and bone concentrations at sites such as FLK *Zinjanthropus* are palimpsests of both hominin and predator activities. He contended that the site was marginally attended

by hominins, whose activities were limited to scavenging carcass parts from carnivores. Binford's alternative idea was supported by evidence of large mammalian carnivore feeding traces at the sites, including gross gnawing of bones (Bunn 1981; Potts and Shipman 1981; Potts 1988).

Nonetheless, Binford's criticisms kicked off a flurry of controversy about mode of carcass acquisition by Oldowan hominins. Whether hominins actively hunted large animals or scavenged the leftovers of predator kills is still a hotly debated issue, as are the specific activities that resulted in the creation of the archaeological sites (Binford 1981; Bunn 1981; Potts and Shipman 1981; Blumenschine 1986).

Since the publication of Charles Darwin's "The Descent of Man" in the nineteenth century, the theory of "Man the Hunter" has pervaded popular and scientific literature. Hunting seems nobler than scavenging and, at first glance, more bountiful, predictable, and safe. Scavenging is perceived to be marginal, opportunistic, and dangerous. What better way to reaffirm our evolutionary success than to portray our early ancestors as mighty hunters?

Binford's proposed hominin scavenger idea led to various alternative hypotheses about the evolution of Oldowan hominin foraging behaviors and functions of the purported living sites. Bone surface modifications became central in this debate because they are the most definitive traces for determining whether carnivores or hominins had primary access to carcasses at these archaeological sites (Binford 1981; Bunn 1981; Potts and Shipman 1981; Blumenschine and Selvaggio 1988). Subsequent studies in the 1990s and 2000s have recognized tooth marks of animals other than large mammalian carnivores such as crocodile, chimpanzee, and human. Despite cautionary notes about possible superficial mimicry of stone tool cut marks and percussion marks by other agents of bone modification (Njau 2012), identification of marks on bone surfaces continues to play a critical role in the interpretation of hominin carnivory behavior in the archaeological record.

Among the proposed interpretations of Olduvai sites includes the "stone cache" hypothesis by Potts (1988). According to Potts, the Olduvai sites were simply places on the landscapes with pre-positioned concentrations of stones where hominins brought carcass parts for quick processing. Other alternative interpretations offered include routed foraging (Binford 1981), central-place foraging (Isaac 1978), dry season-riparian woodland scavenging (Blumenschine 1986), and carcass processing locus (Njau and Blumenschine 2012).

These competing explanations of site function and associated hominin behaviors, however, are still debated. This is because the spatial resolution of the landscape contexts of occurrences was too coarse to understand the ecological settings of hominin activities and activity traces. One problem was that researchers focused analysis on single sites (e.g., isolated dense clusters of stones and bones). As such the ecological contexts of hominin activities and land use behavior were not evaluated on a broad landscape scale (or beyond excavated sites).

Geological, paleontological, and taphonomical studies place the FLK *Zinjanthropus* site in a lakeshore context that has been variously interpreted as grassland, woodland, spring, and marshland (Hay 1976; Ashley et al. 2010). Despite much attention to this topic, many paleoanthropological studies were unable to provide specific ecological contexts of hominin activities. Reconstruction of specific habitats is critical for understanding patterning of hominin land use across paleolandscapes because, theoretically, the distribution of positive resources (e.g., potable water, animal and plant food, refuge trees) and negative resources (e.g., predation hazards, volcanic ash, disease) defined land use. These ecological factors can potentially predict patterns of hominin activities on the landscape as well as the traces of their activities.

The recent basin-wide analyses of Olduvai paleolandscapes (e.g., Lower Bed I, Middle Bed I, Upper Bed I, Lowermost Bed II, and levels immediately above basal Bed II) suggest that dense clusters of animal bones and stone tools at sites such as FLK *Zinjanthropus* do not represent isolated living sites but rather are part of a broad prehistoric land surface utilized extensively by

Oldowan hominins (Blumenschine et al. 2012). For example, the intensive stratigraphic, sedimentological, and paleoenvironmental work on Middle Bed I in the eastern portion of the paleolake margin have identified three landscape facets (a river channel, peninsula, and wetland settings) at the FLK area (Blumenschine et al. 2012; Stanistreet 2012). These lakeshore landscape facets are distinctive geomorphologically and ecologically, and they probably afforded hominins different and predictable types of resources (e.g., animal and plant food, climbable trees, shade trees, hazards). This study shows that hominin activities in the FLK area were focused on the "peninsula" and on the "edges of the wetlands" in general, and not at the FLK *Zinjanthropus* site in particular (Blumenschine et al. 2012).

The peninsula setting provided multiple places, which served as temporary loci where hominins frequently but hurriedly processed carcass parts abandoned there by large predators or foraged from the margins of the wetlands. Probably, hominins accessed the peninsula through the riparian corridor on the FLK Fault footwall (Blumenschine et al. 2012). The treed peninsula afforded shade and refuge from terrestrial predators. Therefore, the accumulations at the FLK *Zinjanthropus* site represent hominin activity traces at one of these relatively safe loci. Nevertheless, the peninsula and wetland edges would have also attracted ungulate prey and their concomitant predators, thus exposing hominins to high predation risk. It is, therefore, implausible that early hominins would have centered daily foraging and social activities of breeding groups at these localities (Njau and Blumenschine 2006).

Indeed, evidence of carnivore damage on hominin bones (White 1988; Njau and Blumenschine 2012) and non-hominin bones (Potts 1988) is well documented at FLK *Zinjanthropus* and other Oldowan hominin sites. It is argued that biologically active settings such as peninsula and wetland edges were also characterized by high predation risks. Therefore, just like other animals, early hominins were preyed upon or scavenged by predators (Njau and Blumenschine 2012). For example, all hominin individuals including specimens of the famous *A. boisei* skull (OH 5) found from FLK *Zinjanthropus* site bore carnivore damage. With the exception of a tooth (OH 44), other hominin materials bearing carnivore tooth damage are the cranial bones (OH 6) and leg bones (OH 35) of *H. habilis* (White 1988; Njau and Blumenschine 2012), suggesting the vulnerability of hominins to predation.

In sum, increasingly new geomorphological, paleobotanical, and paleontological data obtained from Olduvai suggests that the lake margin environments during the Plio-Pleistocene times did not provide safer place for hominins to conduct the full range of maintenance and social activities such as a typical hunter-gatherer home base (Stanistreet 2012; Blumenschine et al. 2012). Although this view is still debated, other studies contend that the clusters of bones and tools represent only irregular, brief feeding activities by possibly small subgroups of nonbreeding individuals who obtained and processed food for consumption there or transport elsewhere (Njau and Blumenschine 2012).

Although various studies confirmed that hominins made stone tools and butchered animals at the FLK *Zinjanthropus* site (Bunn 1981; Potts and Shipman 1981), the evidence is not conclusive as to what extent early hominins engaged in complex social activities such as sharing of food transported to a home base inhabited by a social group throughout successive days and nights. This landscape ecological approach for interpretation of the archaeological record suggests that if hominin home bases existed during the Oldowan times, they were located at safer sites not discovered yet in the greater Olduvai paleo-basin.

Olives: Origins and Development

Charlene Murphy
Institute of Archaeology, University College London, London, UK

Basic Species Information

The olive (*Olea europea* L.) tree is a subtropical evergreen plant that was indigenous to the Mediterranean Basin, confined by its intolerance of frost. It has adapted to long summer droughts and a semiarid temperate climate, well-drained soils, moderate-to-low pH (below 8.5), and mild soil salinity (Terral et al. 2004: 64; Doveri and Baldoni 2007: 254–255). The genus *Olea*, belonging to the family Oleaceae, currently consists of more than 20 species found in tropical and subtropical areas over five continents. Recent revisions of the taxonomy surrounding *O. europea* suggest that this species should be divided into six subspecies based on morphology and geographical distribution including: (1) subsp. *europea* with two botanical varieties *europea* (cultivated olive) and *sylvestris* (wild olive), which is widely distributed throughout the Mediterranean Basin; (2) subsp. *cuspidate* distributed from SE Asia to SW China as well as the Arabian peninsula through East and South Africa; (3) subsp. *laperrinei* is restricted to the Sahara region; (4) subsp. *maroccana*, which is restricted to Morocco; (5) subsp. *cerasiformis* restricted to the island of Madeira; and, (6) subsp. *guanchica* which is restricted to the Canary Islands.

The olive tree is a prickly, long-living evergreen, reaching heights of 15 m and a branch spread of up to 9 m. The olive tree's dense foliage is composed of elliptical-shaped leaves that are gray-green in color. Olive trees can have life spans of more than 500 years, with a few reaching 2,000 years (Doveri and Baldoni 2007: 254). In advanced age, the olive tree trunk becomes hollow, acquiring its characteristic pattern of pronounced twists and protuberances on its bark and continues to add girth to its circumference. The hermaphroditic olive flowers are wind pollinated. Most trees are self-incompatible but a few are self-compatible (Doveri and Baldoni 2007: 254). *Olea europea* L. is the only species that produces edible fruit (Manousis and Moore 1988: 7). The olive is an oleaginous, one-seeded drupe with the fruit yielding up to 50% of its weight in valuable edible oil. Technically, the olive stone (endocarp) "is a fusiform, unintegumented and sclerified endocarp, composed of two asymmetric valves [separated by a longitudinal suture line] protecting one seed"

(Terral et al. 2004: 64), with the surface covered in longitudinally aligned furrows.

The olive tree does not bear fruit for the first 10 or 12 years (Finley 1973: 31). The olive fruit takes 6–7 months to develop fully. The fruit grows slowly over the spring and summer months. A faster increase in size takes place in the autumn due to the water content. Restriction of fruit development can occur if exposed to prolonged droughts. The weight of an individual olive can vary between 1 and 15 g. Oil deposition within the fruit starts at the beginning of the month of August, increases throughout the autumn, and then reaches its peak during November–January when the fruit turns completely black. Harvesting takes place in the autumn after the dramatic increase in size has occurred and the fruit starts to change color. For oil-producing olives, harvesting takes place when the olives are completely ripe, during the months of December or January, to permit the olives to obtain their maximum size and oil content. The commonest method of extraction of the oil from the pulp involves putting the fruit through mills of the edgerunner type (Manousis and Moore 1988). Modern and traditional methods of olive oil production crush the entire olive fruit including the stone to increase oil production as the broken edges of the pit continue to grind the olive fruit, releasing more oil and facilitating the flow of the oil (Tyree and Stefanoudaki 1996: 175).

Subjected to intense climatic and anthropogenic manipulation, the olive tree is considered one of the most versatile and essential crops of the Mediterranean (Terral 2000: 127–128; Costantini and Giorgi 2001: 246; Jashemski et al. 2002; Warnock 2007: 1). Olives were the primary source of edible fat in the Mediterranean used in cooking, soap manufacturing, ointment, perfume, fuel for illumination, and medicine (Finley 1973: 31; Meyer 1980: 405; Costantini and Giorgi 2001: 246). During Roman times, there were about 20 different kinds of olive being cultivated in Italy, Spain, and North Africa; these differed in the shape; size; color of the olive fruits, from nearly white to green, violet, and deep purple; and, in the shape and size of the leaves, from small linear-laceolate to large ovate. Recent studies have shown olives contain antioxidants in abundance, represented by acteosides, hydroxytyrosol, tyrosol, and phenylpropionic acids (Doveri and Baldoni 2007: 255).

Major Domestication Traits

It is believed that oleaster (*Olea europaea* Linn. var. *sativa* DC) represents the progenitor stock from which the cultivated plant derives, which was endemic across the Mediterranean region and the Middle East (Doveri and Baldoni 2007: 253). The domestication of olives has led to the selection of olive trees with larger fruit size and higher oil content under vegetative propagation from either cuttings or grafting to indigenous oleasters (Doveri and Baldoni 2007: 253). The earliest signs for the domestication of olives are generally attributed to the areas bordering the east coast of the Mediterranean Sea during the Chalcolithic period from the fourth millennium BCE in Palestine (Zohary and Hopf 1993: 141 in Zohary 1994: 62–63; Terral et al. 2004: 64). Olive domestication in the Near East is thought to have occurred in early Bronze Age, second half of the fifth millennium BCE, based upon the discovery of olive oil presses and the presence of pollen grains, olive stones, and wood remains (Doveri and Baldoni 2007: 253). Olives have been discovered from the third millennium BC sites in Palestine and Syria and Bronze Age (3rd–2nd millennium BCE) sites in Cyprus, Greece, and northern Italy (Renfrew 1973). By the middle and late Bronze Age, olive cultivation and olive oil production seems to have been well established throughout the countries bordering the east shore of the Mediterranean Sea including Palestine and Syria to Greece (Zohary and Spiegel-Roy 1975: 187). Recent molecular analysis based upon nuclear and cytoplasmic markers from both eastern and western Mediterranean populations found that these two populations are strongly differentiated from one another (Doveri and Baldoni 2007: 255). There are now over 80 different kinds of olive

trees grown in the Mediterranean Basin (Newberry 1937).

It is not possible based upon palynological data to distinguish between wild and domesticated olives (Galili et al. 1997: 1141; Ciaraldi 2001: 172). Olives possess a high degree of variability in the size of the olive stone (endocarp) and it impossible to distinguish between the wild forms and those of cultivated varieties (Liphschitz et al. 1991: 441; Kislev 1996; Zohary and Hopf 1988 cited in Galili et al. 1997: 1141). Recent genetic work has created genetic markers of *O. europaea* which would potentially allow for the germplasm identification of olives, even with the use of poorly preserved material from herbarium specimens or archaeobotanical material (Besnard et al. 2003). Due to their preferential preservation, olive stones (endocarps) are fairly ubiquitous and usually recovered from most Mediterranean archaeological sites (Finley 1973: 31; Terral et al. 2004: 63–64).

Timing and Tracking Domestication

Domesticated olives were brought to the New World in the fifteenth century by Europeans. This was the first time that the olive tree was cultivated outside the Mediterranean Basin. Today, the olive is grown commercially in Australia, South America (Argentina and Chile), and South Africa (Doveri and Baldoni 2007: 253). Cultivated olives possess high variability. There are at least 1,275 known cultivars. Many local varieties and ecotypes have contributed to the richness of olive germplasm. Few cultivars are dispersed over widespread areas. The majority of olive cultivars are highly localized (Doveri and Baldoni 2007: 254). Cultivars are mostly diploids with a few tetraploid plants reported (Doveri and Baldoni 2007: 255). Some olive varieties are used for oil and some varieties for food as preserved olives (Feliks and Gilboa 2007: 406). In processed olive fruits, sugar content varied among olive cultivars according to processing conditions (Marsilio et al. 2001: 485) (Fig. 1).

Olives: Origins and Development, Fig. 1 Whole carbonized *Olea europea* (olive) endocarp recovered from Insula VI.I, Pompeii, Italy (scale in centimeters). (Photo taken by author)

Olmec: Geography and Culture

Lilia Lizama Aranda
Manejo Cultural Research Center, Faculty of Anthropological Sciences, University of Quintana Roo, Puerto Morelos, Quintana Roo, Mexico

Introduction

The Olmecs emerged about 1200 BCE along the rivers of Veracruz and Tabasco. The ethnicity of these people now dubbed the spoken Mixe-Zoquean or Mayan language due to lack of archaeological data, but there is no information as far as what the Olmec called themselves. There is a reliable register about their cities they founded and a list of gods worshipped. One of these gods is represented with incised flamed eyebrows found within an extensive region; for about 1000 years, these symbols and gods were used as a way of communication across a large region. Individuality, self-confidence as exact observers of nature, and self-empowerment for manipulation rose among the population as shamans and priests, for some theorist's population was divided into at least two main social classes to include commoners. Shamans developed a systematic cosmology to explain creation, origins of humankind, and used the human body and nature to explain it. Olmecs occupied a vast tropical rain forest where felines, eagles, caimans, and snakes

complemented practices and rituals. They observed a parallelism of humans with consumers of flesh that also became elements for sacrifice, bloodletting, pilgrimages, cave ritual, offerings of caches, quadripartite vision of the world, and fascination with mirrors (Miller and Taube 1993: 15).

The subject Olmec is to be divided into two parts: (1) the Olmec art style and (2) the Olmec area surrounding the Tuxtla Mountains. The art style has been reported as far away as Peru. The main Mesoamerican sites where Olmec art has been found outside the Olmec heartland are Chalcatzingo and Oxtotitlan.

The most important Olmec sites are La Laguna de los Cerros, Tres Zapotes, San Lorenzo, and La Venta. Most of the literature up until the 1960s is covered in Ignacio Bernal's *El Mundo Olmeca*. Much of the later material on the Olmec sites can be found in the supplements to the *Handbook of Middle American Indians*. San Lorenzo rose probably around 1200 BCE but gets destroyed around c. 900 BCE, about the time La Venta began to flourish (800–300 BCE). The three-site settlement pattern is laid out based on bilateral symmetry, just as their art, symbolism images, and representations are along a central axis.

There is still a general consensus that the Olmec was the fount of all later Mesoamerican civilizations. However, William Sanders in his *Mesoamerica* (with Barbara Price) insists that formative developments in the valley of Mexico were far more sophisticated than the Olmec materials. This goes along with his notion (and the ideas of many others) that central Mexico dominated all of Mesoamerica throughout history (Edward Kurjack, "personal communication").

Definition

The name Olmec is a modern corruption of Olmecatl (Nahuatl "rubber people" or "people of the rubber country"), by which the Aztecs referred to the inhabitants of the region during the Late Postclassic period. Authors like G. Lowe note five main phases of development, but that is in the Formative and Middle Formative periods starting in 1500 BCE, when it starts taking off, and by 1200 BCE coincides with San Lorenzo's growth and development. Its emergence as an important cultural power in southern Mesoamerica and its ultimate decline at the beginning of the first millennium BCE La Venta replaced San Lorenzo during the Intermediate Olmec phase (900–600 BCE) and climaxed in subsequent Terminal Olmec times. Tres Zapotes and other sites located northwest of the Tuxtla Mountains came into power in Epi-Olmec (300 BCE–1 CE) times while under the strong stylistic influence of societies on the Pacific coastal region of Chiapas and Guatemala.

La Venta contains the first radial pyramid ever built within Mesoamerican architecture, which has been interpreted as a volcano effigy. In this site, Olmecs buried pavements and caches in this radial patter, while in San Lorenzo, basalt sculpture was buried along the edges of a large ceremonial platform. Olmecs built thrones or shrines and colossal heads from which lords talked to shamans. Olmec art has not found a parallel prototype in the world, as a unique and complex art of early civilization.

The Olmecs extended from Central America to western Mexico, particularly in search of scarce highlands resources like jade. According to John Pohl, there are four main Olmec sites along a line of 100 miles from the Atlantic coast of the Gulf of Mexico; La Laguna de los Cerros y Tres Zapotes are found in the high elevated lands surrounding the mountains of Tuxtla, while San Lorenzo y La Venta are found between the alluvial plain of the rivers that drains into the ocean. Each site monopolized salt, clay, limestone, and hematite as they were exchanged with squash, beans, and corn, which allowed San Lorenzo development, and La Venta to become a ceremonial center by 800 BCE.

Magnificently carved stone sculptures are the hallmark of Olmec culture. Stones quarried in the Tuxtla Mountains, some weighing many tons, were transported over distances of more than 150 km by water and land. The corpus of sculptures includes colossal human heads that may be portraits of rulers, huge flat-topped "altars," or thrones; realistically depicted life-size human figures; and a bewildering assortment of human,

animal, and intermediate forms that combine traits of both. Scores of monuments must have been displayed simultaneously at every large Olmec center, but since few if any have been found in their original placement, it is impossible to know how they were arranged.

A unique Olmec style is evident in both the monumental sculptures and the smaller portable objects of jadeite, serpentine, clay, and other materials. According to Coe (1965), "the Olmec style is strongly contrasted with all other Middle American styles" not only in its iconographic content of baby-faced, snarling were jaguars and cleft heads but in its formal qualities of shape, line, and space. Their style was so distinctive as its components and pieces display that it can be readily attributed to Olmec artisans regardless of where the object was discovered in modern times.

Olmec commoners lived in small villages indistinguishable from those of earlier times, but the newly emergent elites along with their dependents and retainers occupied larger settlements that we can justifiably call towns. These communities became the foci of economic power, political influence, and religious leadership. Many such towns probably existed, but only San Lorenzo, La Venta, Laguna de los Cerros, and Tres Zapotes have been studied by archaeologists. Not only were these towns larger than the subordinate villages surrounding them, they also contained stone sculptures; temples and elite houses placed on the summits of earth mounds; and buried caches and offerings containing discarded monuments, greenstone celts, and figurines as well as other rare and highly prized objects.

Key Issues/Current Debates/Future Directions/Examples

The heart of the Olmec style has been debated vigorously for decades. Most authorities believe that it grew out of an earlier artistic complex indigenous to the Olmec heartland but executed in wood, cloth, and other objects that have failed to survive the ravages of time. Not everyone agrees, however, and some scholars still seek its antecedents in Guerrero, Oaxaca, Chiapas, or other regions of southern Mesoamerica. For example, if we look at the Göbekli Tepe site and the shrines of the Stone Age, in High Mesopotamia, there is evidence of a "hunter and gatherer" civilization, who also built amazing fine stone large slabs with art work sculpted in it. This evidence is forcing theories of early civilizations that do not necessarily explain the evolution of art and religion as being part of a complex society, in the whole sense of the word, but to explain more simple societies – where art gave shape to religious temples – and before the conformation of complex societies.

Striking evidence of early civilizations such as the Olmec has taken specialists like Matthew Stirling (1939) to uncover the most early dates written in the calendar called the Long Count prevalent among the Maya; nonetheless, Tres Zapotes and its Stela C lacked this type of calendrical note; Stirling correlated the date to 32 BCE, similar in time to other reading of Long Count found at Chiapa de Corzo in Tuxtla Gutierrez and La Mojarra Stela 1, depicting a standing lord wearing the principal deity headdress and regalia as those of the Maya kings. This evidence has resulted in the beginning of a formal tradition not only attributed to the Olmec but the whole in Mesoamerican art, representing the dynastic generations of rulers, registration of time with the use of calendars, and phonetic writing.

Author Richard Diehl (2004a, b) expresses that these civilizations are special kinds of human societies that have appeared only infrequently in the human past. They are more complex than the smaller-scale, simpler societies that preceded them. Their defining characteristics include complex social hierarchies, economic structures, and political systems; clearly defined territories or spheres of influence; "capitals" that were larger than the satellite communities subordinate to them and that, in some cases, true cities or urban centers, with high attainments in the arts. Architecture, calendrics, religion, ritual, written and oral literature, and other branches of esoteric knowledge that according to him reflect the presence of an upper class or elite, perhaps the trait that most distinguishes civilizations from their less complex and organized predecessors.

This take to consider findings like well-preserved wooden sculptures and objects of rubber and other perishable materials immersed in a permanently wet spring over 40 wooden busts carved out of soft wood and feature faces stylistically identical to Olmec carvings in stone, wooden scepters shaped like serpents, rubber balls, and over 100 greenstone celts that such early symbols marked the rest of ideology and Mesoamerican symbology of royal power like that shark's tooth mounted on the wooden serpent mouth scepters. An object's deliberate placement in the bottom of the spring, perhaps as offerings to a water deity sometime after 1000 BCE might make theorists formulate comparisons with distant areas, like those large heads carved at Eastern island, and the Classic Maya site of Ek Balam, this site exposing a behavior of deliberate hiding of an 8 m sculpture in decorated exterior facade of a temple that showed some of the finest stuccoes art work ever to be found within the region.

Theories hold that Olmec society contained at least two social strata: a small ruling elite and a much larger group of commoners forming large work parties; perhaps numbering in the thousands, the commoners constructed earthen mounds, transported basalt from quarries in the Tuxtlas, and carried out other projects requiring the efforts of entire communities. Monuments depict rulers wearing sumptuous capes, headdresses, jewelry, and other articles of clothing symbolic of their high status. Rulers controlled long-distance trade and exchange systems that supplied them and their supporters with obsidian, serpentine, jadeite, pottery, feathers, iron ore ornaments, and other raw materials and luxury goods that enhanced their prestige. Goods and materials that came from central Mexico, Morelos, Guerrero, Oaxaca, coastal Chiapas, and Guatemala were probably paid with cacao, jaguar pelts, crocodilian skins, stingray spines, and an array of finished products in the Olmec style.

Key issues are that most scholars agree that the Olmecs "influenced" their neighbors and later Mesoamerican civilizations but the nature and extent of their impact is the subject of spirited debate (cf. essays in Sharer and Grove 1989). Some maintain that the Olmecs were Mesoamerica's mother culture, the precocious base civilization that set the example for its less highly developed neighbors. Others maintain that Olmec societies were no more complex than their contemporaries elsewhere in Mesoamerica and that the widespread occurrence of Olmec motifs and stylistic conventions result from ideas and practices in many areas, rather than diffusion from a single Olmec source. Similarly, some authorities stress the continuities, especially in art, ideology, and religion, between Olmec culture and later civilizations, while others emphasize the differences that appeared during the later evolution of urban life.

For example, by 900 BCE, Copan down in the Maya raising civilization made imitations of Olmec ceramics and jade, while in western Mexico, Olmecs encountered with the Xochipala culture where naturalistic human figures had been made after 1500 BCE. Olmec-style petroglyphs also mark the cliffs of highland Guatemala and Chiapas, established a center at Teopantecuanitlan, Guerrero, and Olmecs performed rituals in caves at Cacahuazqui, Juxtlahuaca, and Oxtotitlan as well in Guerrero.

Some of the Oxtotitlan paintings, dating late Middle Preclassic period c. 800–500 BCE, were investigated by Dr. David Grove in 1968 and 1969. The paintings appeared in detail in several publications in Spanish and English. Scenes depicting simple geometric designs, large polychrome murals were executed on the cliff face. One painting depicts a personage wearing a bird mask and bird-feather cape. The bird mask has traits suggesting that it represents a horned owl. The personage is seated atop a large supernatural serpent face. The size of this painting is 3.8 m by 2.5 m. The graffiti and damage caused by past visitors has been eliminated, and many of the paintings have been carefully cleaned and preserved. In addition, the villagers of Acatlan have assumed the important role of caretakers and guardians of the cave and its paintings. The cave is open to public, but it is now protected by a large fence with locked gates, and people wishing to visit the cave must first register at Acatlan's municipal palace in order to gain access.

David C. Grove declares that because of its elaborate and precocious bas-relief rock art dating to c. 700–500 BCE, Chalcatzingo, Morelos, has long been recognized as one of Mexico's most important Formative period archaeological sites. For decades, scholars noted the close similarities between Chalcatzingo's rock carvings and the monumental art at distant Olmec centers on Mexico's southern Gulf Coast. However, the nature of Chalcatzingo and the "Olmec presence" there remained unclear. Had it been an Olmec colony? A trade control center? In the 1970s, the Chalcatzingo Archaeological Project, codirected by Jorge Angulo, Raul Arana, and David Grove, sought to gather data on the Formative period village – its dwellings, public architecture, and material culture – in order to better understand the site's evolution and also its relationship with the Gulf Coast Olmecs.

Chalcatzingo possesses monumental architecture, consisting of earthen platform mounds sometimes faced with stone, and began appearing in Mesoamerica around 1300 BCE during the Early Formative period (1500–900 BCE). The site is located 120 km southeast of México City in the state of Morelos, at the base of two large hills on the only good expanse of agricultural land for many miles. Chalcatzingo provides a unique opportunity to investigate the form and function of monumental architecture since it is the only known central Mexican site with evidence of monumentality in the Early Formative period.

Investigations on Chalcatzingo's settlement pattern, environment, agricultural practices, trading patterns, and social organization led to questions like, do the platform mounds serve as substructures for chiefly residences or public buildings? What are the types of activities associated with these platform mounds? How did these platform mounds change over time? The data yielded by the excavation of the platform mound was also used to examine theories of the rise of sociopolitical complexity at Chalcatzingo.

Results lead to believe that platform mounds served as substructures for the erection of important structures that functioned as a public building or multiple-purpose facilities which served as both temples and chiefly residences. Above all, monumental architecture is significant for the understanding of sociopolitical development as indicators of an inegalitarian social organization which marked its status and power through monumental constructions during the Early Formative of Mesoamerica.

Monument 32 similar to Monument 21 depicts a woman wearing elaborate clothing, holding her hands in a similar pose, and standing in front of a column. The two monuments appear to be mirror images of one another, perhaps representing a male and female who were related in some way. Cyphers Guillén (1984) has indicated the portrayal of a woman on Monument 21 commemorates a marriage alliance between the elite of Chalcatzingo and a nearby area and has identified this site as Teopantecuanitlán, Guerrero. The male personage on Monument 32 may be her marriage partner and may also come from this locale.

Long sequence of occupation of this site preceded and postdated the platform mound. Whether it was built through voluntary communal effort or under the direction of a particular individual, the platform mound indicates the existence of a centralized authority.

Analysis of the ceramics, figurines, and other artifacts associated with the platform demonstrates a similarity with materials from other sites in the Valley of México during the same period of time which indicated independent development of sociopolitical complexity at Chalcatzingo. This contradicts previous theories which postulated that cultural development at this site was the result of contact with the Olmec culture of the Gulf Coast (Piña Chan 1955; Coe 1965; Bernal 1969).

Domestic architecture, subsistence practices, food-preparation techniques, refuse disposal patterns, level of technology, economic practices, craft production, and other aspects of daily life have not been under study and form part for future studies. Only a handful of Early Formative houses from Central México have been excavated.

Omoto, Keichi

Saitou Naruya
National Institute of Genetics, Mishima, Japan

Basic Biographical Information

Keiichi Omoto, Ph. D., professor emeritus of both the University of Tokyo and International Research Center for Japanese Studies, was born on May 16, 1933, in Tokyo. His father was a professor of electrical engineering at the Tokyo Institute of Technology. Since childhood Omoto was enthusiastic about butterfly collecting, which gave him a motivation to study the diversity rather than the laws of nature. After 2 years in the General Culture Course of the University of Tokyo, he went to the Faculty of Letters and majored in German Literature. During this period, he attended a special lecture on human evolution given by Professor Hisashi Suzuki at the Department of Anthropology of the Faculty of Science. Suzuki encouraged Omoto to study Physical Anthropology in his Department. After graduation in 1956, Omoto entered the Faculty of Science and majored in Physical Anthropology. Accordingly, he has two bachelor degrees: a

Bachelor of Arts (literature) and a Bachelor of Science (Physical Anthropology). He entered the master's course of the Graduate Course of Science in 1959, at the University of Tokyo. After he obtained a Master of Science degree, he proceeded to enter the doctoral course. After finishing his coursework, he obtained a scholarship from the German government (DAAD). In 1961, he entered a Ph.D. program at the University of Munich that specialized in human genetics. His academic supervisor was Professor Karl Saller. Keiichi Omoto studied genetic polymorphisms of serum proteins using agar and starch gel electrophoresis. He received Ph.D. from the University of Munich in 1963. He then obtained the scholarship from the Alexander von Humboldt Foundation and moved to the Department of Human Genetics, University of Freiburg, Breisgau, where his supervisor was H. W. Goedde. In 1964, he returned home in Tokyo and was appointed as a research assistant in the Department of Anthropology, Faculty of Science of the University of Tokyo. Omoto received the Doctor of Science degree from the University of Tokyo in 1972 based on the doctoral thesis "Blood protein polymorphisms and the problem of the genetic affinities of the Ainu." Accordingly, he has two doctoral degrees: a Ph.D. (Munich) and a D. Sc. (Tokyo). Omoto became a lecturer and an associate professor at the same Department in 1968 and 1973, respectively. He was promoted to full professor in 1979. Starting a year before his retirement from the University of Tokyo in 1994, he served as a professor in the International Research Center for Japanese Studies in Kyoto from 1993 to 1999. He also served as a professor at Momoyama Gakuin Daigaku (St. Andrews University) in Osaka from 1999 to 2004. He was then invited to be a senior research fellow by Graduate University for Advanced Studies (Sokendai) in Hayama and managed a research team for human growth study from 2004 to 2010. He is now living in Tokyo with his wife.

Major Accomplishment

After he returned to Japan from Germany in 1964, Keiichi Omoto was involved in an anthropological study of the Ainu people in Hokkaido, the northernmost island of Japan, as a part of the International Biological Program (IBP). Together with Shogo Misawa, a doctor of the legal medicine who specialized in blood group typing, Omoto collected blood samples from the Ainu people in District of Hidaka, Hokkaido. He analyzed allele frequency data of blood groups, serum proteins, and red cell enzymes when he was a visiting research fellow at the Australian National University, Canberra, in 1970 (e.g., Omoto 1972). Later, he also studied indigenous people in Okinawa, the southernmost islands of Japan. Omoto and his collaborators collected a large number of blood samples in the 1970s and the 1980s from various indigenous peoples of the Philippines, especially focusing on the ethnic groups belonging to the negrito (small black) people, and published a series of papers on their genetic characteristics (e.g., Omoto et al. 1978; Omoto 1984). He also studied various ethnic minorities in Hainan Island and in the northern part of China in the 1980s and the 1990s with Chinese collaborators (e.g., Omoto et al. 1993). Later, Omoto carried out a series of data analyses (e.g., Omoto 1995; Omoto and Saitou 1997) with special reference on the origin of Japanese and the negrito peoples. When genome-wide SNP typing became available, the DNA samples of the Ainu and the negrito people that had been collected by Omoto were used. These massive data presented new perspectives on modern human evolution in East Eurasia (Japanese Archipelago Human Population Genetics Consortium 2012; Jinam et al. 2017, respectively). Omoto published many books written in Japanese, including *Human and Civilization* (2016). Because this encyclopedia focuses on archeology, Omoto's other academic activities have not been mentioned so far. However, he is well known as a butterfly

collector in Japan, and his collection is now stored in the University of Tokyo Museum as the "Omoto Collection." He also carried out molecular phylogenetic analyses of butterflies using mitochondrial DNA data and published papers in the journal *Gene*. He is also good at playing shogi (Japanese chess) and holds a high rank in this.

Ontologies

Artur Ribeiro
Institute of Pre and Proto-History, University of Kiel, Kiel, Germany

Introduction

Ontology and thinking in ontological terms has become a widespread phenomenon in recent years, crosscutting several social sciences, with a particularly strong impact on archaeological studies. In the most general of terms, ontology focuses on the world (or worlds) as it is. This turn to ontology is a reaction to the claim that archaeological reality is best understood when subsumed under epistemological principles, social theorizing, and cultural relativism. For the supporters of ontology, archaeological theory of the twentieth century was too limiting in that it artificially separated reality into its material manifestation and knowledge of that manifestation. This dual way of perceiving archaeological reality is an affectation of modernist ways of reasoning, one that sees reality as perpetually divided between being/thought, nature/culture, and subject/object. Against this, ontological perspectives promote approaches to archaeological reality by recognizing its ontologically real, inherently material, and intricately connected nature.

While ontological perspectives are theoretically quite diverse and have been influenced by a vast array of authors and disciplines, they nevertheless agree that the theoretical standards and practices of the previous century are inadequate. They criticize the idea that archaeology should focus on humans and argue that there is more to archaeology than recognizing the "web of interpretations" weaved by human actors. Ontological perspectives place archaeology closer to current trends in anthropology, to approaches developed in science and technology studies, and political ecology.

Methodologically, ontologies favor credulity and wonder in face of that which goes against our westernized, rational, and modernist view of reality; they favor approaches which perceive reality as built upon relations between objects (human and nonhuman); and they also favor the exploration of the material properties of objects, and how these properties change and are changed in their own emergence.

Definition

There are several definitions of the term "ontology" in archaeology, but these can be reduced to two main definitions. The more recurrent one is that found in the work of Benjamin Alberti (2016) which is adapted directly from the "ontological turn" in anthropology (Henare et al. 2007; Viveiros de Castro 2012). According to Alberti, rather than concerning the "world as it is," which is the conventional definition of ontology as understood in philosophical circles, ontology as applied in anthropology comes from indigenous theory and concerns the actual world of the people under analysis, rather than their worldview. More concretely, the ontological turn suggests that the differences between different human groups are more than just differences in how people perceive or know the world. Thus, instead of thinking in terms of epistemology, it is preferable to recognize reality in terms of ontological difference. It should be noted that this definition has not gone uncriticized, with some scholars pointing out that there seems to be little difference between "ontology" and "culture" (Carrithers et al. 2010).

A second definition of "ontology" comes from a metaphysical trend in archaeology, which claims some links to anthropology, but also distances itself from it in certain ways. This understanding of ontology is metaphysical in that it pays respect to the work of philosophers, rather than from anthropological studies of the previous definition. Based on the work of thinkers such as Bruno Latour, Jane Bennett, Karen Barad, among many others, archaeologists have started discussing ontology as the basis on which archaeological research should be conducted. While there are some similarities between this definition and the previous one, there are also crucial differences. On the one hand, the term "ontology" in the anthropological sense has clear methodological connotations insofar as it forces the anthropologist and/or archaeologist to abandon Western epistemological choices, which are often imposed on informants (e.g., differentiation between humans and animals) given that these choices tend to have little or no applicability in non-Western contexts. On the other hand, the term "ontology" in the current metaphysical trend in archaeology refers not to the "world" of informants, but rather to the general foundation on which reality exists. In this sense, ontology is closer to its philosophical origins as it concerns whether the world is composed of objects (Edgeworth 2016; Olsen 2010), relations (Watts 2013), or vibrant matter (Crellin 2017).

The term "ontology" is also used quite loosely to refer, at times, to the commitments followed by archaeologists in their research. In this sense, ontology concerns the objective conditions that underlie how archaeological research is conducted. For instance, Harris and Cipolla claim that most archaeological research of the twentieth century followed a dualist ontology, one which was subsumed under opposing elements such as nature/culture or mind/matter (Harris and Cipolla 2017: 27ff.). This, in turn, has led to an artificial separation of archaeological research into two poles, one that favors the study of signs, subjects, beliefs, identity, and culture, and another pole which favors the natural sciences, materials, and objects. The advocates of ontological approaches recognize that not only is this separation too artificial, it is very unlikely that people in the past recognized reality in this dual way. Against this, advocates of ontological approaches recommend dismantling these dualisms and favoring an understanding of reality which recognizes all elements as interrelated, as parts of networks, entanglements, or assemblages. This non-dualist way of recognizing reality would allow a deeper and more detailed understanding of reality, one which recognizes how humans and nonhuman objects mutually affect one another.

Historical Background

As is common with theoretical notions, it is difficult to pinpoint an exact moment when ontologies were first addressed in archaeology. If we accept that ontology refers to the objective commitments followed by archaeologists in their research, then it can be said that ontology has been a crucial element of archaeology since the birth of the discipline. However, if we are more concerned with the study of ontologies themselves, it becomes possible to historically trace when and why ontologies became important to archaeologists.

Ontology was not something that just sprung up in archaeology and anthropology out of nowhere – it has had a long gestation period outside these disciplines. Given that the concept is of philosophical origin, it comes as no surprise that it is in philosophy where the concept rose to prominence in the years preceding its archaeological and anthropological adoption. From a historical perspective, it can be said that ontology has always been a crucial element in philosophical thought. In fact, throughout history, we witness several philosophers or schools of philosophy provide ontologies as foundation for their systems of thought. This means that in many schools of philosophy, ethics, epistemology, logic, etc. can only be understood in relation to an ontology. This is not to say that all philosophy focuses on ontology, in fact, most schools of philosophy tend to ignore it or outright reject it. This is what happened during the early twentieth century when language philosophy and logical empiricism came into prominence. For these two schools of philosophy, ontology and/or anything metaphysical was to be rejected.

In continental Europe however, metaphysics and ontology remained quite popular, especially through the work of Martin Heidegger, but only up until the rise in popularity of philosophical thinkers such as Michel Foucault, Jacques Derrida, and Jacques Lacan who shifted the primary concern of continental philosophy from metaphysics to that of language, power, and society.

Outside of continental Europe, it was Roy Bhaskar who first stepped away from traditional language philosophy by addressing philosophy of science as an issue concerning the ontology of the world (Bhaskar 2008 [1977]) and by putting forward a universal ontology which conceives reality as layered. Many scholars, such as Margaret Archer and Anthony Giddens, followed his lead in the UK, and it became standard practice in the social sciences in general to conceive social reality as something involving more than just linguistic and/or normative elements. While Bhaskar's work had little influence on archaeologists (Gibbon (1989) and Wallace (2011) are some of the exceptions), it was without a doubt one of the crucial elements in conceiving society in terms of ontology. Additionally it was Bhaskar who set the stage for the rise of scholars in the UK, the USA, and continental Europe who later on started thinking in terms of ontology. One of these scholars was Bruno Latour who gradually distanced himself from the relativist philosophy of science which was popular in the 1980s and 1990s and proposed conceiving scientific reality as irreducibly ontological, that is to say, a perception of science as an enterprise involving a network of objects, such as neutrons, microscopes, and labcoats, rather than as an enterprise dictated by "worldviews" or "paradigms." Latour has had an impact in the study of ontologies in archaeological research since the early 2000s, with archaeologists adopting a wide array of his ideas from his actor-network theory (see Jones 2001) to his critique of modernity (see Martin (2013) and Witmore (2007)). Around the same time that Latour started gaining prominence in archaeological circles, a growing dissatisfaction could be felt against the interpretive archaeology of the 1990s which many viewed as too anthropocentric and idealist. As argued by Jones et al., the greatest problem of interpretive archaeology is that it perceives the human as the center of the universe, an interpreting subject surrounded by representations of objects. According to this view, nonhuman objects are important insofar as they are interpreted by a human subject (Jones et al. 2013: 19).

The dissatisfaction with this view gave prominence to phenomenological approaches in the early 2000s, which viewed humans as engaging actively with the world rather than just

interpreting it. This led archaeologists to focus more on the material culture in reconstituting the everyday life of peoples and their engagement with their physical surroundings. Bjørnar Olsen has taken this position and expanded upon it by advocating an ontology of objects (Olsen 2003, 2010). As he argues, archaeology is mired down by speculation on the thoughts and lives of past peoples when what archaeology should be focusing on the objects of analysis themselves.

A key set of ideas that has been very relevant to the discussion on ontologies comes from archaeologists who have advocated for a symmetrical ontology (Witmore 2007) or a flat ontology (Harris and Cipolla 2017). Directly influenced by Latour's critique of modernity, the idea of a symmetrical or flat ontology is based on the principle that nonhuman objects and humans are not a priori ontologically distinct, but rather a result of modernist conception of the world. This aligns with the idea that we should not be prioritizing the human interpretation of the world and that objects should, in fact, be favored by archaeological research as suggested by Olsen.

Alongside Latour, from the 2010s onward several new thinkers were added to the roster of contributors. Of these thinkers, Gilles Deleuze, via Manuel DeLanda, has contributed toward a deeper understanding on the relations between different objects through the concept of "assemblage" (Hamilakis and Jones 2017). Jane Bennett has also been a key scholar for archaeologists by expanding Deleuze's argument that agency is not exclusive to humans but rather a vibrant property of assemblages themselves. In addition to these new contributions, a new philosophical trend titled "Speculative Realism" made its way into archaeology. Of the philosophers associated to this trend, the most relevant are Quentin Meillassoux and Graham Harman. According to Meillassoux, there is an inherent principle in all post-Kantian philosophy which is to perceive thinking and being as inherently correlated and never independent from one another, what he has defined as correlationism (2008). As argued by Meillassoux, the only way to overcome correlationist perspectives of reality is to perceive reality through mathematical properties since it is these properties which can be considered to be independent from correlation between thinking and being. Harman's ideas on the other hand are based on the ontology of Martin Heidegger. Like Meillassoux, Harman's object-oriented ontology has the objective of highlighting the existence of objects in their own right and independent from our perception of them. In order for this to be possible, Harman argues that there are two conceptions of objects which must be taken into account: real objects and sensual objects. In gist, Harman argues that all objects as we recognize them are real but constantly withdrawn from us, that is to say, the essence of an object never comes into full contact with humans except through its sensual properties (Harman 2013: 24).

Anthropology's introduction to ontology follows similar to that of archaeology. First, there was a growing dissatisfaction with the representationalist viewpoint, i.e., the idea that all anthropological alterity could be reduced to difference in points of view; and second, the contributions of Latour to our understanding of Modernity and its divides like nature/culture, subject/object, human/nonhuman greatly influenced how anthropologists thought of their own biases with regards to their informants. In anthropology itself, the work of Roy Wagner and Marilyn Strathern were in the 1970s and 1980s, the precursors of the explicitly ontological mode of investigation followed more recently by scholars such as Viveiros de Castro and Martin Holbraad.

Key Issues/Current Debates

Ontology is wrapped up in a good amount of contention with many scholars rejecting key ideas associated to it, rejecting it wholesale, or just outright ignoring it. While it seems that most who have discussed ontologies agree on what should be rejected when it comes to the current *status quo* in archaeological research, there seems to be much less coherence on what should be embraced. Thus, the most glaring problem affecting our understanding of ontologies is the sheer amount of ideas which are either not relevant to the discussion or in direct opposition. As more ontologies are put

forward, it becomes more and more evident that many ideas are not compatible. For example, Quentin Meillassoux critique of correlationism is indirectly a critique of phenomenology. Thus, it means that Meillssoux's ideas are not compatible with those of Martin Heidegger and, by extension, Graham Harman, whose research is directly building upon the work of Heidegger. It comes then, as a surprise to see Meillassoux and Harman cited approvingly side by side (e.g., Edgeworth 2016). Furthermore, while Meillassoux's notion of correlationism has been employed recurrently in archaeological literature, there is no mention of the fact that Meillassoux advocates an approach to reality based on mathematical properties, which he believes to be the only way to overcome correlationism.

A similar issue can be identified when discussing all the elements which can compose an ontology. For example, in his defense of an ontology based primarily on "things," Christopher Witmore claims that things are assemblages, things are participants, and things are things (2014). This type of claim, however, can come off as a bit confusing. Ontology concerns the fundamental make-up of the world, meaning that an ontology should be a description of the world stripped to its most essential elements. By describing the world as a composition of things which are multiple (as assemblages, as participants, as things), Witmore is not really identifying the true composition of reality. This has been one of the more contentious issues surrounding ontological studies in archaeology – deciding which element is most fundamental to an ontology. For instance, both in philosophy and archaeology, there is a debate whether precedence should be given to relational networks in which things are participants or whether precedence should be given to things in-themselves regardless of their position within networks. The lack of a clear and definitive ontology and its composition shows that, despite the popularity of ontologies in archaeology, there is still little common intellectual ground.

There is also criticism that focuses not on ontologies themselves but on what we ultimately mean when we talk about humans and humanity. One of the recurrent claims involved in ontological studies is that humans should not be given ontological priority, that is to say, that humans are ontologically indistinct from nonhuman objects. Given this ontological "flatness" or "symmetry," archaeologists should support the idea of an archaeology dedicated toward the care, obligation, and loyalty to things, as opposed to an archaeology dedicated to the study of past human lifeways. This claim, however, has been subject to much discussion and criticism with many scholars outright rejecting it. For example, John Barrett has pointed out that regardless of whether humans and nonhuman objects are ontologically distinct, humanity follows a historical trajectory very much its own (Barrett 2014). Thus, what matters is not the metaphysical composition of humans and objects but the processes through which they came into existence and made themselves via their relations with one another.

Additionally, it has been pointed out that there is an overt and subtle anthropocentrism subsisting in ontological studies despite recurrent claims that anthropocentrism has been rejected. This issue is most evident when human actions and properties are used to describe nonhuman objects. For instance, Severin Fowles has noted that much of the ontological literature places nonhuman objects in the position of "interpreters" of their relations with other objects, transforming them into ethnographic informants (Fowles 2016).

Another issue is that of ontological pluralism. According to certain anthropological circles, there has been concerns as to whether pluralizing ontologies is not just cultural "relativism" in disguise. As Alberti has argued, the existence of several ontologies does not necessarily reflect "relativism" since ontologies are not the same as interpretations of a knowing subject (Alberti 2016: 168). This means that there are not multiple interpretations of one singular world, which would make truth and objectivity difficult to attain, but rather plural worlds, which relate to one another. Although this an interesting perspective on ontology, it is not free of problems: as Paolo Heywood points out (Heywood 2012), would this not entail imposing ontological pluralism onto indigenous groups who do not necessarily believe in ontological pluralism?

Finally, the most recurrent criticism of ontological studies comes from those who remain faithful to classical methods and theories from social studies. While supporters of ontologies see their ideas as valid replacements of the ideas advanced by social theory, supporters of social theory on the other hand have criticized ontological studies for failing to address power, norms, ethics, and politics in their explanations. According to these social theorists, the lack of coherent explanations on how power and moral beliefs motivate actions precludes the supporters of ontology to address real-world problems such as hunger in third world countries, wealth inequality, human trafficking, or the refugee crisis. This comes, in part, from supporting ontologies which promote "flatness" or "symmetry": by failing to see moral differences between different actors, the idea of responsibility becomes relativized and consequently, the task of identifying the "responsible actor" for a certain state of events becomes nigh impossible.

Future Directions

Thinking in terms of ontology has opened many new doors in archaeological research in the past 10 years, but it has also encountered an inordinate amount of obstacles in its way. A big part of the problem comes from keeping discussions on ontology too dependent on philosophical debate, and less on archaeological and anthropological practice. While there is some work which does manage to bridge some of the more abstract ideas associated to ontology and how archaeologists commonly interact with archaeological reality, many doubts remain on the efficacy of ontological approaches. The current debates on ontologies are mostly about philosophical premises, and on this issue, it is important that the supporters of ontological claims quickly reach some consensus concerning what key ideas and premises should be supported. Furthermore, it becomes increasingly important for the supporters of ontologies to establish a clear and concise link between the abstract philosophical discussion with archaeological practice. It is through the application of methods and perspectives associated to ontologies that the importance of ontology can really shine through. There are already some examples of these practices; however, they remain too few and far between for the rest of the archaeological community to accurately judge the advantages of ontology. Overall, for future success, the ontological turn requires:

- A clear synthesis that carefully selects those elements which are essential for a correct and concise understanding of how ontologies can actually improve the state of the art. This will require abandoning some key figures and ideas in ontological studies in favor of others.
- Identify the common ground between the more metaphysical type of ontology of archaeology and the ontological turn which has been advocated in anthropological studies.
- Identify and/or create methods which are compatible with ontological studies.

While these directions might not automatically solve all the current problems, they will nevertheless highlight the importance of conceiving archaeological reality in ontological terms. As stated by Harris and Cipolla (2017), all research is conducted under an understanding of what the world is and how it manifests, and in this sense, thinking in ontological terms is essential as a tool which parses our own research biases and ultimately what it means to practice archaeology.

Oral Sources and Oral History

Brent R. Weisman
University of South Florida, Tampa, FL, USA

Introduction

The archaeological use of oral sources has gained rapid popularity in recent years as archaeologists around the world have recognized the value and need of connecting their research with topics relevant to public interest and to local community concerns. Implicit in much of this orally informed research is the use of archaeology as a means of addressing issues of social justice by empowering marginalized groups "without history" (Wolf 1982) both to create a heritage narrative by and for the people and to insert these multiple narratives into mainstream national origin stories and provide them with a role in these. Scholarly citations in the Web of Knowledge with oral history or oral traditions as keywords greatly increase in the years after 1996 and are few and far between prior to 1994. Historical analysis of the literature indicates that oral sources were being used in some areas at the beginning of organized archaeological research in those regions, Africa (Posnansky 1966; Schmidt 1978) and North America (Cushing 1886) being clear examples. This historical precedence needs to be acknowledged while also recognizing the emergence of distinctively new approaches.

One new trend worthy of attention is in the use of oral sources in the historical archaeology of the twentieth century. A 2009 study of World War II aerial bombardment seeks to link personal experience to collective memory as focused on buildings and physical sites in Germany (Moshenska 2009). A 2003 study uses oral sources in conjunction with ethnobotany, forestry, and archaeology to document recent rainforest regeneration after logging in the Solomon Islands (Bayliss-Smith et al. 2003). Another study integrates spatial data with oral histories pertaining to infant burials in unconsecrated ground (Murphy 2011). These studies indicate that at least some archaeologists

are exploring innovative connections between the material and expressive realms in framing a more human-centric perspective to the scientific practice of archaeology.

The increasing visibility of oral sources in archaeology also serves as a call to revisit fundamental practices and tenets of oral techniques, as archaeologists did not invent this mode of investigation. It is useful to distinguish two kinds of oral sources. This is important because the two kinds employ slightly different methods, theories, and applications. Still, the two are often conflated by both researcher and reader and even by the informant or narrator. The first kind is oral history, which is a record of an individual's personal experience with a past place, way of life, or event. This can be a person's life story as it intersects with the subject of archaeological interest such as at a historic place, in an archaeological site that needs to be evaluated as part of regulatory compliance, in artifacts or objects being evaluated for conservation and preservation and their value in public interpretation, or on landscapes on which now-vanished ways of life once played out. The unit of analysis in oral history is the individual, often referred to as the "informant" or narrator. The informant is one member of a group of "locals," each of whom functions as an individual source of information. The oral history technique is widely used in anthropology (Angrosino 2008), history (Vansina 1965), folklore (e.g., the many volumes of the *Foxfire* series, published by Anchor Press), sociology, and journalism. Archaeologists typically construct oral history interviews to collect information on the appearance and life history of buildings, how artifacts and the tools of technology once functioned, the demographics and social composition of user groups, social relations and ideology, and social meanings attributed to the use of space. To do oral history effectively, archaeologists benefit greatly from basic training in ethnographic methods. They would also do well to remember that the interview is a relationship between two people and can create ambiguity as well as certainty. The usual format is the audio or visually recorded interview, or written notes, which can then be transcribed for study and analysis. In this form other researchers can access the narratives and essentially use them as historical documents. In the USA, for example, the federally supported Works Progress Administration (WPA) collected many volumes of oral histories during the Depression-era 1930s, most of which are readily accessible today in print and online formats.

The second kind of oral source is the oral tradition. Oral traditions are cultural narratives such as origin stories, myths, and legends that are passed down from generation to generation orally as cultural knowledge. Typically, until the intervention of an outside researcher, oral traditions do not exist in written form. Oral traditions comprise a corpus of explanations, values, and historical facts that become the touchstones of cultural identity. Oral traditions can exist in story and song and are sometimes in whole or in part given artistic expression as glyphs on rock faces, as decorative pottery styles, and basically on any surface suitable for bearing an inscription made by the human hand. Oral traditions can be elicited by interviewing an informant, but the events and beings, human and otherwise, typically belong to a time before the informant's direct life experience. Oral traditions thus are a type of culture history and function socially as a binding historical narrative. Further, to the extent that these narratives also provide explanatory knowledge of natural history, cosmology, and physics, they also define an indigenous science. Therefore, the archaeological goals of analyzing the structure and content of oral traditions differ in some respects from the goals of oral history analysis. Unlike oral histories, oral traditions tend to be recounted as received scripts and, although personally variable and potentially idiosyncratic, cannot be further explicated by the informant beyond the initial telling. From the teller's point of view, they are whole and complete in and of themselves. Claude Levi-Strauss is well known, rightly so, for his ability to identify and break down the coded components of traditional narratives into patterned sets of opposing elements (Levi-Strauss 1966), and his structural approach has influenced the archaeological use of oral

tradition, particularly in Africa (Schmidt 1978). Levi-Strauss and most structuralists, including his archaeological disciples, agree that the oppositions that form this deep history are beyond (or beneath) the conscious intellectual repertoire of the human bearers of tradition and cannot be directly elicited through questioning.

Historical Background

The first generation of archaeologists to systematically incorporate oral sources as valid lines of evidence acknowledge the work of Jan Vansina (1965) as their primary source of inspiration (Schmidt 2006). It is not coincidence that Vansina's work and the research of these archaeologists were situated in Africa, which turned out to be a particularly rich location for developing and expanding the use of oral sources in archaeology (Shaw 1977; Schmidt 2006). Vansina, although not an archaeologist, argued that oral sources are expressive cultural messages and can be systematically analyzed to yield insights into cultural and historical process, in essence placing oral traditions within the same analytical frameworks that archaeologists use to understand the relationship between artifacts and the contexts of knowledge in which they were created. Archaeologists responded well to Vansina's comparative and integrated approach that emphasized the evidentiary potential of oral sources when carefully applied to archaeological problems.

Some archaeologists were openly dismissive of the contributions of oral sources to an explicitly scientific archaeology, but others by the mid-1980s increasingly viewed archaeology as being incomplete and even unethical in not including oral sources provided by living peoples whose ancestors created the archaeological record under investigation. In the USA, much of this rethinking initially focused on the relationship between archaeologists and American Indians (Trigger 1980), which has by now resulted in an abundantly rich literature (Swidler et al. 1997; Echo-Hawk 2000; Whiteley 2002; Mason 2006). The formal relations between federally recognized Indian Nations and archaeologists were given structure and legitimacy through federal laws and policies regarding Indian sovereign rights to the objects and places comprising their cultural heritage. Archaeologists employed in federal projects and Indian representatives of Nations whose heritage might be impacted or threatened by federal action (dam building, navigational improvements, highway construction as typical examples) together learned how to engage in the mandated consultation process, one goal of which is to elicit native testimony as to the significance of sites, landscape features, or other elements of material culture that might be incompletely understood or appreciated using standard archaeological and historical techniques alone. By law, oral histories and oral traditions are given equal status with conventional archaeological and historical evidence in determining Indian claims in both the Native American Graves Protection and Repatriation Act (NAGPRA) of 1990 and the Traditional Cultural Property process associated with the legal evaluation of significance (King 2003). These key pieces of federal law and federally mandated regulatory process have fostered a greater acceptance of oral sources by the archaeological mainstream, despite some initial reluctance to yield authority over knowledge of the past. In the USA as the cultural resource management (CRM) industry has matured in response to broader, more inclusive federal historic preservation goals, the use of oral sources has increasingly found its way, almost routinely, into a wide range of efforts aimed at promoting cultural diversity by directing archaeological attention to remains associated with minority, marginalized, or victimized populations. These projects run the gamut of current research themes or problem orientations in historical archaeology and include World War II Japanese-American internment camps and German POW camps in the USA and Canada (http://whitewaterpowcamp.com), coal mining communities (Metheny 2007), pioneer settlements and urban African-American enclaves (Weisman 2011), and immigrant populations facing the challenges of relocation (Hornung 2002).

Key Issues/Current Debates

The use of oral sources is not unique or original to archaeology. Other social sciences and humanities disciplines have developed a body of method and theory to guide the use of what for them is one of the major sources of data for their scholarly inquiries. The challenge for archaeologists is to use oral sources to both critique and expand conventional archaeological research designs in an integrative approach that demonstrates the inextricable connection between material culture and expressive culture. Clearly what is found in the ground and what comes from an informant's mouth are cultural products and reflect the interaction between individual agency and social constraint. Archaeologists through middle-range theory and increasingly sophisticated understanding of postdepositional effects on the archaeological record have taken an appropriately critical view of direct or simplistic behavioral interpretations. Likewise, they also need to develop a critical approach to the use of oral sources. As a source of data, oral histories in particular need to be problematized and subjected to analytical rigor. As Vansina cautions, oral history is the product of human memory (1965: 147), and it can be created in numerous ways to serve the subject's interests. The invention of a personal history that coincides with or articulates with larger historical events is a well-known human penchant. Further, eyewitness accounts can be clouded by smoke or dust or fear. Being in the middle of an action as it is unfolding is no guarantee of veracity and rarely affords a panoramic, distanced perspective. Personal narratives can intentionally or unintentionally fail to disclose crucial circumstances or can absorb and then repeat collective narratives in the guise of individual experience. Clearly there is skill involved in reconstructing personal and cultural realities from such narratives. Careful attention must be paid to the rigor and intellectual discipline in order to establish credibility and defensibility. Investigators must also be aware of their own biases and internalized ethnocentrisms that might privilege etic data or physical evidence over emic or internal expressions (Schuyler 1978). Archaeologists face a further challenge in giving equal footing to oral sources and the archaeological record in developing their interpretations. Some archaeologists envision a conversation between the two data sources in which contradictions or discrepancies generate new questions and enrich the potential for truly original research design (Beck and Somerville 2005). This approach, valuable in refreshing the perennial but occasionally lapsing concern with method and theory, essentially repeats the process engaged in years ago by historical archaeologists as they struggled to reconcile history's written record with what was found in the ground. As such, archaeologists should now recognize fully that oral history is a form of history, perhaps even history with a capital H, and can be subjected to textual analysis. This critical approach is of ever-increasing importance to counter any tendencies to romanticize oral sources or elevate their importance over other forms of evidence, especially if one of the goals of modern archaeology is to build synthetic, systemic, and integrated models of the human past.

New opportunities for the innovative use of oral sources will emerge as archaeologists endeavor to theorize the concept of memory as it can be investigated materially. The study of memory is gaining ascendancy in the humanities and social sciences research, meaning memory as something culturally constituted and possessed collectively or, alternatively, memory as the historical reality experienced and defined individually. This is an area that lends itself to true interdisciplinary research and to which archaeologists can uniquely contribute. Archaeologists can link both places and things to ideas about places and things carried around in people's heads and by so doing can add insights to the broader understanding of how people create the realities of their own existence through both conceptual mental frameworks and the physical structuring of space. Using places generatively to confront or prompt memories essentially as a locus of oral history production is one step toward an "archaeology of emotion" (Murphy 2011) and attempt to fundamentally reposition oral history with archaeology. Archaeologists engaged in these practices are now recognizing the complexities in assigning meanings to social phenomena that are inherently ambiguous (Mullins 2014; Olsen 2003).

International Perspectives

The use of oral sources in archaeology is most widely advanced in areas of the world where archaeologists have explicitly attempted to bridge and reconcile the historical and cultural erasures of colonialism through increased access to the archaeological record by indigenous peoples. Archaeologists working in these regions and sympathetic to the goal of connecting indigenous peoples to a past severed by colonial practices tend to view access to history as a human rights issue and the use of an indigenous-centered archaeology as one means of redressing human rights abuses. The USA (Swidler et al., Echo-Hawk 2000), Canada (Clark and Clark 1974; Stewart et al. 2000) Africa (Raharijoana 1994; Schmidt 2006, 2016), and Australia have particularly well-developed literatures in which oral sources are seen as inseparable and foundational in the development of truly indigenous archaeologies which are both empowering for the native peoples and supported by national legislation. In considering the junction of oral history and archaeology as one source of a multiple historical approach to studying Mayan populations in Guatemala, Metcalfe (2005) brings to our attention the ethical considerations in deliberately eliciting information from indigenous groups that is then restructured into Western definitions of archaeological space and content. Indeed, this can be seen as the modern version of cultural appropriation simply dressed up in the latest jargon. Metcalfe also cautions that the process of converting oral histories into scholarly research and publication brings with it, unavoidably, a shift in context that might transform or recast their original meanings and purposes. In South America, archaeologists from the US National Museum of the American Indian are using oral traditions and archaeology to develop community-level heritage projects focused on the historical and cultural significance of the Inka Road. More synthetic approaches in the historical archaeology of South America use North American methods and theory as a model and suggest that oral sources present a largely untapped potential (Funari 1997).

Europe and the UK have an emerging literature focusing on public traumas and civil strife of the recent past. Archaeologists working in Jordan have used Bedouin oral histories to address deficiencies in nomad archaeology (Simms and Russell 1997), while Caribbean archaeologists have attempted to engage modern African-descended populations with the places of their colonial past (Scudder-Temple 2009).

Many archaeologists around the world have seen the need to connect and communicate with indigenous peoples as increasingly evident and are seeking to equalize the relationship between authority derived from academy and science-based expertise and the traditional knowledge possessed by people typically cast in the "subject" role. Most of these archaeologists seek risk in foregoing the benefits and value of science and seek to balance the contributions from oral sources with those gained from traditional archaeology. Debates will continue as to how and if this balance can be achieved.

Future Directions

One of the main goals of using oral sources in archaeology is to construct a locally contextualized model of past reality that is relevant to participants, engages contemporary communities, and verifiably contributes to the broad knowledge of the human experience. Truly integrating oral sources into an archaeological research design with the level of theoretical and methodological sophistication present in other disciplines will require new approaches in training future archaeological professionals. The credibility of the oral source as a line of archaeological evidence and its ultimate acceptance as a core archaeological practice require rigorous application by trained professionals. The question then is: How to train students to be both theoretically and methodologically adept at applying an integrated ethnographic and archaeological skill set in the areas of basic research, cultural resource management, and heritage stewardship? This cross-training is not easily accomplished in the traditional academic silos in which most of the future

professionals continue to be educated (Castaneda and Matthews 2008). Many academic archaeologists already face the reality of having to submit an application for oral history research to their Institutional Review Board (IRB) or, as often referred to in European institutions, "Ethics Committee," because oral history is categorically defined as social-behavioral research and informants considered as subjects. In most cases, such research is regarded by the IRB as posing minimal risk and therefore qualifies for expedited review; nonetheless the IRB experience should not be the first and only exposure to the ethics of ethnographic research.

At present there is no unified theory shared by all archaeologists who use oral sources in their work. Some archaeologists continue to use oral sources for the conventional purpose of improving the discovery and interpretation of archaeological sites and features (David et al. 2004), while others seek to use oral sources creatively to bring new perspectives and new research questions to the archaeological record (Bernardini 2005). Some relegate oral sources to a minor supporting role in confirming alleged archaeological facts, some place the two in conflict with each other hoping that the contradictions will yield new insights, and some strive to put archaeology and oral sources side by side as parallel streams of knowledge flowing toward a larger cultural synthesis. There remain two camps of archaeologists: those who respect oral sources and bring them actively into their research and those who are deeply skeptical of any claimed continuity between the present and past as expressed through oral sources. These two strains run deep in the history of archaeology and have ebbed and flowed through time. While it seems likely that there are more archaeologists working today than ever before and that the global opportunities for archaeological research are at an all-time high, it also appears that the archaeological use of oral sources is enjoying a rise in popularity and in new, innovative forms. Undoubtedly not all of these attempts will stand the test of time, but the challenges they present will stimulate greater future awareness of the role of oral sources in archaeology.

Oral Tradition: Ancient Greece

Barry B. Powell
Department of Classics, University of Wisconsin-Madison, Madison, WI, USA

Introduction and Definition

Oral tradition refers to cultural material transmitted orally from one generation to another without the aid of writing. It may take many forms: jokes, sayings, narrative poetry, songs, folktales, genealogies, and praise poetry. In this way, laws, prescriptions, and even historical elements are transmitted. But principally *oral tradition* refers to poetic composition and, as such, is called "oral theory" or "oral-formulaic theory." Oral tradition is distinct from the study of orality, which has to do with the nature of thought and expression in illiterate societies.

Historical Background

The study of oral traditions began in the nineteenth century with the Serbian scholar Vuk

Stefanović Karadžić (1787–1864), of peasant origins. Vuk Karadžić was a linguist and reformer of the Serbian written language, especially its orthography, bringing it closer to common speech and away from Serbian Church Slavonic. He is called the father of Serbian folklore because of his famous collections of folk songs, fairy tales, riddles, and proverbs. His studies were characterized by the same national interests as those of his contemporaries Jacob and Wilhelm Grimm, who knew Karadzic; in the culture of the folk was thought to lie the true soul of the people.

Vasily Radloff (1837–1918), a German-born Russian and the founder of the scientific study of Turkic peoples, followed up Karadzic's work with studies of the songs of the Turkic Kara-Kirghiz in central Asia. Radlov was a founder of the museum of ethnography in St. Petersburg. The work of Karadzic and Radlov provided models for the work of Milman Parry (1902–1935), creator of the oral-formulaic theory.

Milman Parry was born in Oakland, California, and studied classics at the nearby University of California in Berkeley, where he earned a BA and MA. Even as an undergraduate, Parry became interested in the Homeric Question, that is, where did the Homeric poems come from, the earliest poems in the Western tradition? These are the *Iliad* and the *Odyssey* from probably the eighth century BCE, always ascribed to a man named Homer about whom nothing is known. How did they come into being? Parry's discoveries were to revolutionize not only Homeric studies but also the study of many other literatures. While influenced by Vuk Stefanović and Vasily Radlov, his work made direct use of the insights of Marcel Jousse at the Sorbonne (1886–1961), who studied the anthropology of gesture; Matija Murko (1861–1952), a Slovene scholar who worked on south Slavic epics and whose publications in French Parry studied in Paris; and Arnold van Gennep (1873–1957), the founder of folklore studies in France, famous for his work on rites of passage. But Parry's discoveries were to go far beyond the work of any of these men.

When Parry began his work, the prevailing view of Homer was that the poems were the result of a long period of accretion and editorial redaction. The poems had been "stitched together" (an inaccurate understanding of the word "rhapsode" as "stitcher") from many shorter poems by unknown hands, perhaps in the sixth century BCE in Athens during the reign of the Peisistratids. This position was called Analysis, as opposed to the minority Unitarian view, which held that the poems were the creation of a single intelligence at a single time. Whereas the Analysts made use of narrative and logical inconsistencies, of which there are a good number, to establish the lines of demarcation between allegedly originally separate poems, the Unitarian position looked past such flaws in a theory of unitary composition.

After receiving his M.A. at Berkeley, Parry traveled to Paris in 1924 and enrolled at the Sorbonne, where he studied under the great linguist Antoine Meillet (1866–1936). In 1923 Meillet had written the following (quoted in Parry's first French thesis 1925):

> Homeric epic is entirely composed of formulas handed down from poet to poet. An examination of any passage will quickly reveal that it is made up of lines and fragments of lines which are reproduced word for word in one or several other passages. Even those lines of which the parts happen not to recur in any other passage have the same formulaic character, and it is doubtless pure chance that they are not attested elsewhere.

Meillet thought that this feature might be distinctive of orally transmitted epic (such as the *Iliad*) and suggested to Parry that he observe a living oral tradition to find out if his suggestion was accurate. He introduced Parry to Murko, who had made phonograph recordings of Serbo-Croatian heroic epic and written extensively about them. Murko sat in on Parry's Ph.D. defense and recommended that he travel to then Yugoslavia. Parry did just that in 1933–1935, with his assistant Albert B. Lord (1912–1991), and assembled the largest collection of field recordings ever made–12,500 dictated texts and sound recordings on more than 3,500 aluminum discs. Today the collection, of which only a portion is published, is housed in the Widener Library at Harvard University.

Up to the fieldwork of Parry and Lord, the theory of the oral origins of the Homeric texts

had depended on a rigorous analysis of the text, but the theory was justified by Parry and Lord's unprecedented experiment in the real world. Parry argued that Homer, like the Serbo-Croatian poets, composed orally by means of "formulas" instead of our "words." He defined a formula as "a group of words which is regularly employed under the same metrical conditions to express a given essential idea" (Parry 1971). For example, such phrases as "rosy-fingered dawn" (*eos rhododaktylos*) or "wine-dark sea" (*oinops pontos*) or "much-suffering divine Odysseus" (*polutlas dios Odysseus*) or "gray-eyed Athena" (*glaukôpis Athena*) or "swift-footed Achilles" (*podas ôkus Achilleus*), or "glancing-helmed Hektor" (*koruthaiolos Hektor*) occupy a certain portion in the metrical line and enable the singer (Greek *aoidos*) to compose rapidly. Such formulas are characterized by "thrift," that is, there is only one such formula with a certain metrical pattern occupying a certain place in the line. Such a system could not be the creation of one man, but must depend on a tradition to which the singer had access. The formulas did allow internal substitutions and adaptations in response to narrative and grammatical needs, a flexible pattern that fit varying situations, and eventually Parry formulated the notion of a "formulaic system" that contained both a constant and a variable element.

The purpose of such a system of ready-made diction was to enable composition in performance, so that traditional features of Homer's language became proof for its oral origins. The thesis seemed to explain the highly unusual *Kunstsprache*, the "artificial language" or curious so-called epic dialect that incorporated features (especially Aeolic) alien to Homer's otherwise Ionic dialect. No one ever spoke this dialect, but it must have emerged over a long period of time through exposure to various dialectal forms that proved useful to the construction of the poetic line. Such features are unknown to such demonstrably written texts as Apollonius' *Argonautica* or Vergil's *Aeneid* and could only have come into being through the generations as a collective inheritance of many singers, Parry thought.

Parry died before he could compare systematically the technique of South Slavic poetry with Homer's, and his work attracted little attention until the publication in 1960 of *The Singer of Tales* by his assistant Albert B. Lord, perhaps the most influential work of literary criticism of the twentieth century. Parry's work was gathered together and published by his son Adam Parry in 1971 as *The Making of Homeric Verse*. In the *Singer of Tales*, Lord widened the comparative investigation to include medieval English, medieval French, and Byzantine Greek literature. Together with examples of formulaic language in South Slavic epic, he described such other features of oral traditional style as the *type scene*, or "theme," and the story patterns that governed whole epics. Lord also wrote about the singer's apprenticeship, describing his study under a master as a young boy to the time of his mastery of the craft.

Parry and Lord worked with an assistant named Nikola Vujnovic, himself a singer, and conversations between him and other singers shed considerable light on the process of oral composition. We think of poems as being made up of words, but linguists cannot define a "word" except as something found in dictionaries. The concept "word" is a product of literacy. When asked "what is a word" (*retch* in Serbo-Croatian), one singer replied as follows (Foley 1995):

Nikola: Let's consider this: "*Vino pije licki Mustajbeze*" ("Mustajbeg of the Lika was drinking wine"). Is this a single *retch*?
Mujo: Yes.
Nikola: But how? It can't be *one*: "*Vino-pije-licki-Mustajbeze*."
Mujo: In writing it can't be one.
Nikola: There are four *retchi* here.
Mujo: It can't be one in writing. But here, let's say we're at my house and I pick up the *gusle* (the one-stringed instrument that accompanies heroic song) – "*Pije vino licki Mustajbeze*" – that's a single *retch* on the *gusle* for me.
Nikola: And the second *retch*?
Mujo: And the second *retch* – "*Na Ribniku u pjanoj mehani"* ("At Ribnik in a drinking tavern") – there.

In short, for the illiterate singer, a "word" is a unit of meaning, not a typographical convention

that depends on the technology of writing. Further questioning revealed that by *retch*, the singer could mean several lines, a scene, or even a whole poem.

Parry's noun-epithet formulas, such as "much-suffering divine Odysseus" (*polutlas dios Odysseus*), function in much the same way as units of composition that combine with other phrases to constitute a hexameter line. The noun-epithet formula is metrically suitable for combination with various phrases containing a verb. Together they make up a whole line. Such is true of hundreds of noun-epithet "words" for people and gods in the *Iliad* and *Odyssey*.

On a broader level, poets working in the tradition use type scenes, or "themes," to build the overall poem. We might say that the "words" are whole type scenes, standardized in outline but flexible enough to fit the immediate context. For example, in the *Odyssey*, when somebody arrives for a feast, there is always a seating of the guest, a servant brings water for washing, a table is placed before the guest, a servant provides bread and other foods, and a carver hands around meat and gold cups. Then:

> They put their hands to the good things that lay prepared before them,
> but when they had put aside their desire for food and drink . . .

Though these details are common to all scenes of feasting, a very different use is made of them in the feast of the suitors, of Odysseus on Circe's island, and of Telemachus at the house of Menelaos in Sparta, a reflection of the flexibility of the Homeric traditional style.

Typical type scenes in Homer include Battle, Travel, Speeches, Messenger Speeches, Dreams, Divine Visitation, Conference, Assembly, Supplication, Dressing, and Seduction. All such scenes can be fleshed out or compressed in accordance with the dramatic requirements of the narrative. Such type scenes are common in the south Slavic epic that Parry studied, as well as the general theme of return, also attested in the traditions of medieval England, nineteenth-century Russia, Albania, Bulgaria, Turkey, and central Asia.

Key Issues/Current Debates

The theory of oral composition was used to explain the various narrative inconsistencies of which Analysts had made so much, for the dictating poet has no way to go back and correct "errors" nor any interest in doing so. It also explained the use of such unsuitable epithets as "blameless Aegisthus" to describe the murderer of Agamemnon, or "swift-footed Achilles," while he sits calmly in his chair. It also could explain the inordinate length of the Homeric poems, because when an oral poet dictates his text, freed of the exigencies of a live performance, free to elaborate his tale at will, the songs can become very long. The *Iliad* and the *Odyssey* are far longer than any ordinary oral poem.

Lord devoted a good deal of effort to the work of a Bosnian singer from Montenegro named Avdo Međedović (1875–1973), who did dictate a poem about the same length as the *Odyssey*, called *The Wedding of Smailagic Meho* (which Lord translated, 1974: see http://www.youtube.com/watch?v=8buaCDlYU2U). Not only was the poem about the same length as the *Odyssey*, but the story is similar. A young man comes of age, he is called to marriage, there is a great battle, and in the end there is wedding. The poem far outstrips typical performances by Avdo's peers in both length and artistry. The example proved that the *Odyssey* could have come into being in just this way, as a dictated text. Such has become orthodoxy in a modern understating of the genesis of Homer's poems.

Oral Theory was initially criticized because it appeared to make the *fons et origo* of Western literature a slave to a mechanical system. Where was room for poetic invention and genius if the lines are made up of preset expressions? The contribution of individual creativity appeared to be submerged in a collective poetic tradition. However, the units of expression that Parry and Lord identified in oral verse are no more restrictive on expression than the large but finite store of words (in a conventional sense) in literate traditions. The oral-formulaic language is just that: a language, subject to the morphological and grammatical restrictions of any language.

Another criticism of the Parry-Lord oral-formulaic theory questioned the validity of the analogy between Serbo-Croatian epic and Homer, pointing to the greater "metrical strictness" of Homeric poetry and its higher quality in general. But differences in quality, whether or not they are real, depend on the skill of the composer and not on the technology he is using.

International Perspectives

The work of Parry and Lord has been applied to many other literatures, both living and in textual form, including Medieval English, Medieval French, African, Native American, and Chinese. Already in 1953, Francis P. Magoun (1895–1979), Albert B. Lord's dissertation adviser at Harvard, published a famous essay on Beowulf, "The Oral-Formulaic Character of Anglo-Saxon Narrative Poetry." In it Magoun argued that Anglo-Saxon poetry was a transcription of traditional oral performance, heavily imbued with pre-Christian values. In a related development, the Canadian media theorist Marshall McLuhan (1911–1980) began to concentrate on how communicative media shape the content of the message.

McLuhan was advisor to the Jesuit Walter Ong (1912–2003), whose interests in cultural history resulted in *Orality and Literacy* (1980), which has had considerable influence. Ong drew heavily on the work of the Anglo/American Eric A. Havelock (1903–1988), who had suggested a shift in the form of thought coinciding with the transition from "orality" to "literacy" in Ancient Greece. Writing is a technology like other technologies (e.g., fire, the iron plow, the internal combustion engine). Ong considered that when introduced to what he called a "primary oral culture" (which has no writing), writing (he means alphabetic writing) produces wide-ranging effects on economics, politics, art, and other cultural forms. Ong thought Literacy changes people's mentality, causing "interiorization" and "individuation." Without writing, people must depend on proverbs and other forms of condensed wisdom in order to make legal and moral decisions. Epic poetry provided stylized culture heroes, for example, the wise old Nestor, the clever Odysseus, or the brave Achilles. Writing allows far more individualized models for behavior.

Ong distinguished between "primary oral cultures" (which have never known writing), "craft literacy" (where scribes hold the power), and cultures with a full literacy (such as our own), in which however there may still exist a "residual orality." In primary oral cultures, thought is cyclical whereas in literate culture it is linear, historical, or evolutionary. In the modern electronic age, Ong distinguished a "secondary orality" that lives alongside writing in which a new orality is sustained by telephone, radio, television, and other electronic devices that depend for their existence on writing. Ong's works widened what we understand as oral tradition by accounting not only for the creation of literary artifacts (the preoccupation of Parry and Lord), but for their reception.

Another scholar important to the study of oral tradition was John Miles Foley (1947–2012), founder of the journal *Oral Tradition* (http://journal.oraltradition.org/) and the Center for Studies in Oral Tradition (1986) at the University of Missouri. Foley consolidated oral tradition as an academic field that brought together scholars working in disparate academic fields (but primarily ancient Greek, Anglo-Saxon, and Serbo-Croatian). Foley introduced the concept of "traditional referentiality" by which he explained the meaning of such epithets as "swift-footed Achilles" as summing up, through reference to the tradition, the whole character of Achilles. Therefore, "swift-footed Achilles" did not mean just "Achilles," as Parry thought, but embodied the whole essence of his personality.

As the study of oral tradition progressed, a great difficulty was faced in scholars' inability to define clearly what was meant by a "formula." Noun-epithet formulas were easy to find, but other formulaic expressions slipped away as one tried to pin them down. The term "formulaic system" was suggested, which contains "substitution slots" for syntactic, morphological, and narrative needs, but in fact research into the formula proved a dead end. Such could only have been the case,

just as the attempt to define a conventional "word" has proved impossible. Language is a flexible medium depending on invisible templates that generate the form on the surface. For this reason, the many attempts to define the "formula" proved ineffective, because language is not mechanical, but a human faculty whose origins and functioning are poorly understood.

Future Directions

A persistent problem with those dealing with the oral-formulaic theory and the dichotomy orality/literacy is the failure to understand that "literacy" is not a single thing. By "literacy" commentators always meant "alphabetic literacy," not understanding that there are many other kinds of literacy, for example, that prevalent in ancient Egypt or in China today (Eric Havelock did have an inkling of this). Barry B. Powell has argued that the invention of the Greek alphabet made possible a very special kind of literacy, and that it was inspired by the desire to record the *ipsissima verba* of Homer himself (Powell 1991, 2003). The strongest evidence for this thesis comes from several factors: (1) the correspondence of the apparent dates of Homer, probably the eighth century BCE, and the invention of the Greek alphabet around 800 BCE; (2) early inscriptions, which are preponderantly hexametrical; (3) the absence of references to writing in Homer (except once, where he does not understand it); and (4) the history of writing. The Greek alphabet was the first writing that could actually be pronounced, even by a non-native speaker. All other forms of writing provide only hints of the actual sound of the language represented and, in the case of Chinese, scarcely even that. The Greek alphabet was the first system of writing capable of preserving Homer, and it is odd that it actually did this if that was not the purpose of its design.

Therefore, in thinking about literacy's effect on human mentality, on its promotion of linear over cyclical thinking, for example, or on its encouragement of philosophical thought, one must remember that alphabetic literacy is a very special form of literacy invented with the express purpose of recording oral poetry. Conclusions based on it cannot be extrapolated easily to the literacy of ancient Mesopotamia, where in fact there was no philosophy. Powell argues furthermore that "orality" is nothing as such, with special qualities, and that "literacy," being very different in different cultures, has different effects, always elusive and hard to define.

The study of oral tradition has in any event been widened since the work of Parry and Lord to include philosophy, cognitive science, linguistics, communication theory, semiotics, biblical studies, communication theory, popular culture, film study, and many other fields. The recognition of oral tradition as the source and basis of the alphabetic literate tradition has profoundly altered our understanding of the past.

Orce: Early Pleistocene Archaeological Sites

Luis Gibert
Department of Mineralogy, Petrology and Applied Geology, University of Barcelona, Barcelona, Spain

Introduction

Orce is the name of a town in SE Spain (province of Granada) rich in Early Pleistocene archaeological sites. Venta Micena (VM), Barranco León-5 (BL-5), and Fuente Nueva-3 (FN-3) are localities of special interest because the archaeological and paleontological evidence shows human occupation between 1.3 and 1.2 Ma. BL-5 and FN-3 have supplied a large collection of Oldowan tools associated with vertebrate fauna (Fig. 1). In addition, a fragment of a deciduous human molar was found at BL-5 site (Fig. 2), and later, a complete deciduous human molar was recovered from the same layer in 2002 (Gibert et al. 1999; Toro-Moyano et al. 2013). Recent studies showed that both deciduous molars belonged most probably to the same individual (Ribot et al. 2015). Venta Micena does not show lithic tools, but antropic action on bones has been described associated with three fragmentary human remains and fauna (Gibert et al. 2006a).

Definition

Barranco León (BL-5)

The deposit of Barranco León-5 is located in a fine sand bed varying in thickness between 10 and 25 cm that belongs to the distal part of a small alluvial system. BL-5 is a classical paleontological site, above layers BL-1 to BL-4, but is the only one that has supplied lithic tools to date (Gibert et al. 1992a, 1998; Roe 1995; Tixier et al. 1995; Toro-Moyano et al. 2013). In 1995 a deep quarry (>12 m) was excavated to reach the archaeological level. This first excavation revealed a lower mandibule of hippopotamus surrounded by more than hundred lithic artifacts associated with the following fauna: *Castillomys* cf. *crusafonti, Mimomys* sp. *Allophaiomys pliocaenicus, Equus granatensis,* and *Hippopotamus amphibious antiquus.*

Barranco León produced in 1995 114 lithic artifacts, 112 of flint 1 of quartzite and 1 of Jurassic limestone, and 20 manuports also from Jurassic limestone. Subsequent excavations have increased the faunal list and the lithic collection to more than 1000 tools (Fajardo 2008; Toro-Moyano et al. 2010, 2011). The flint from BL-5 is of good quality and is mostly gray in color although a yellow-brown variety is also present. The flint cores and flakes are small within a range of 20–61 mm with a mean of 40.7 mm. The butts have a very variable morphology, and the flakes are not usually cortical. Chopper cores of flint and limestone are also present in BL-5.

Orce: Early Pleistocene Archaeological Sites, Fig. 1 Tools from BL and from FN-3. View of Oldowan tools (unretouched flakes) from Barranco León-5 and Fuente Nueva-3. Those tools were unburied during field season of 1995, and all of them are made from local flint although from different sources

Orce: Early Pleistocene Archaeological Sites, Fig. 2 Cut marks and broken bones from VM. This figure shows an example of a bone broken by percussion from Venta Micena; those fractures show a very different pattern than bones broken by carnivores (Gibert et al. 1992a). The same figure show subparallel cut marks from a pelvis from Venta Micena; the view under SEM shows a typical micro-striation usually associated with cut marks and indicates that erosion is affecting equally the surface of the bone and the surface of the cut marks indicating an old origin

The source of the flint and limestone from Barranco León is the Jurassic Sierra de la Umbria and Periate where locally the chert replaces the Jurassic marine limestones. Blocks of quality flint (up to 10 cm) are concentrated in alluvial fan deposits down on the valley, only 2 km SE the site, behind the town of Orce.

Fuente Nueva-3

FN-3 site is located between Sierra de la Umbria to the South and Cerro de la Venta to the NE, in a marginal zone of the basin. Lithic artifacts were initially identified during a survey by Dr. J. Gibert and J. Serrallonga in 1991, later more artifacts and fossils appeared when the electrical company was carrying out work nearby (Gibert et al. 1992a).

The location of the site and a small assemblage of nine artifacts from Fuente Nueva-3 were first described in Gibert et al. (1992a), and more details on 23 artifacts can be found at Tixier et al. (1995). The first extensive excavation was developed during summer of 1995, when more than 100 lithic artifacts were recovered associated with *Mymomys* sp., *Allophaiomys pliocaeinucs, Equus granatensis, Hippopotamus amphibious antiquus, Mammuthus meridionalis,* and *Bovini indet.* The majority of the lithic artifacts were closely associated with remains of large mammals in three distinct archaeological levels. Those levels are affected by soft sediment deformation probably induced by earthquakes.

More than a hundred lithic artifacts were discovered during this initial excavation, mainly from level FN-3a. >90% of these artifacts are made with local flint although some tools of quartzite and Jurassic limestone were also identified. In addition, 20 manuports of Jurassic limestone were uncovered. Successive excavations increase the number of lithic tools and faunal list (Fajardo 2008; Toro-Moyano et al. 2010, 2011).

In Fuente Nueva-3 the flint is of uniform white color and of good quality, with some pieces having secondary iron oxide staining. Identified cores have centripetal flaking, their mean length is 65 mm, while the flakes range from 21 to 64 mm with a mean of 59 mm. Flakes have a plain striking platform and some shows probable use traces. A chopper core of quartzite was probably used as a hammerstone, to judge by abrasion on the cortical face (Gibert et al. 1998b).

Fuente Nueva-3 flint has a different origin than BL-5, and its source is still unclear; the closest sources for quartzite from BL-5 and FN3 are the Late Miocene fluvial deposits outcropping 6 km NE from FN-3 that probably were exposed during the Early Pleistocene.

The BL-5 and FN3-a lithic assemblages show no important differences. They represent a lithic technology with a very simple *chaîne opératoire*, lacking any sign of bifacial flaking technique; accordingly both can be compared to the Oldowan and even classified as such, being the first well-defined examples of Oldowan in Europe (Gibert et al. 1998b).

Venta Micena

Venta Micena site consists of a rich fossil-bearing layer (80 cm thick) that extends in horizontal lacustrine deposits for >1 km^2. Venta Micena is the richest site in fossil fauna from the Orce region. Between 1982 and 2003, >250 m^2 were excavated from 9 different quarries located on the same fossiliferous layer supplying 2867 dental pieces and 7468 postcranial fossils that correspond to at least 214 individuals (Gibert et al. 2006a). The majority of these finds come from Quarry-3, the only one that has supplied evidences of human presence. The fauna represents at least 32 species of mammals including Homo sp., *Desmana* sp., *Allophaiomys pliocaenicus, Apodemus aff. mystacinus, Castillomys crusafonti* ssp., *Eliomys intermedius, Hystrix major, Prolagus calpensis, Oryctolagus* cf. *lacosti, Ursus etruscus, Canis etruscus, C. falconeri, Vulpes praeglacialis, Homotherium latidens, Megantereon* sp., *Lynx* sp., *Pachycrocuta brevirostris, Meles* sp., *Mammuthus meridionalis, Equus granatensis, Dicerorhinus etruscus brachycephalus, Hippopotamus amphibius antiquus, Praemegaceros* sp., *Cervidae indet., Bubalus* sp., *Soergelia minor, Hemitragus alba, Testudo* sp., *Lacerta* sp., *Rana* sp., *Charadriiformes indet.* (Gibert et al. 2006a). No lithic tools have been identified to date, although pieces of Jurassic limestone were recovered in the micritic-size carbonate deposits and interpreted as transported to the site by early humans (Gibert et al. 1992a). Venta Micena shows three human remains: a parietal-occipital fragment (VM-0), a juvenile human diaphysis (VM-1960), and the mid-shaft of an adult humerus (VM-3961). As is usual in paleoanthropology, these remains generate considerable debate (Gibert et al. 1998a) and opinions (Palmqvist et al. 2005). Specifically the skull fragment VM-0

shows an unusual internal crest that was used by some to classify the specimen as a horse (Agustí and Moya 1987). The identification of similar internal occipital crests in humans and the identification of fossil human proteins in those remains by independent teams from Spain and EEUU close the debate for most of the experts (Campillo et al. 2006; Borja et al. 1997). In addition, evidences of human activity such as bones broken by rock percussion and cut marks have also been described at Venta Micena (Gibert et al. 1992a) associated with evidence of scavengers' activity (Arribas and Palmqvist 1998) showing an interesting competence between early humans and hyenas (Figs. 3 and 4).

Orce: Early Pleistocene Archaeological Sites, Fig. 3 Human molar fragment from Barranco León. This molar shows characteristic human enamel features (Gibert et al. 1999, 2006a). It is compared with a half modern human molar (below right) showing identical enamel distribution. An additional human molar has been described from the same site (Toro-Moyano et al 2013; Ribot et al. 2015)

Key Issues/Current Debates/Future Directions/Examples

Implications

The exceptional sedimentary record from Orce is dated between 2 Ma at the bottom of the Salar and Vélez canyons and ~1 Ma to the top. This section can be completed to the west at Cúllar and Huéscar localities where Middle Pleistocene deposits have been preserved from erosion. Those sections occur 19 km S-SW and 7 km N-NW from Orce and contain the archaeological site of Cullar-1 dated at 0.75 Ma and the paleontological sites of Huescar-1 and Puerto Lobo with ages of ~0.9 Ma (Gibert et al. 2007a). In the same basin but 65 km to the SW, the site of Solana del Zamborino exposes a nice collection of Acheulian tools with evidences of fire that have been dated at 0.75 Ma (Scott and Gibert 2009). In summary, we can say that the Orce region has a long record of human occupation between 1.3 and 0.75 Ma. The presence in SE Iberia of the oldest Oldowan tools and later the oldest evidences of Acheulian tools in Western Europe suggest that the Strait of Gibraltar was a permeable barrier for humans during the Early Pleistocene. This hypothesis challenges classical model of human dispersal from Africa to Europe around the Mediterranean during the Early Pleistocene. Archaeological finds in Soa Basin (Flores Island) indicates that early humans were able to cross marine barriers. In addition, the presence of African primates (*Theropithecus oswaldi*) at the Early Pleistocene site of Cueva Victoria supports a dispersal of fauna through the Gibraltar Strait, probably in a moment when the sea level was low and the distance between continents was reduced substantially (Fig. 5) (Gibert et al. 1995, 2016; Ferrandez et al. 2014).

The Geology

Orce is located in the NE marginal sector of the Baza Basin, in the internal part of the Betic range. A recent geophysical survey reveals the semi-graven structure of this basin filled with marine

Orce: Early Pleistocene Archaeological Sites, Fig. 4 Orce man and two other human bones from VM. This figure shows external and internal view of VM-0 and a humeral shaft classified as human from Venta Micena

sediments until the basin was isolated from the sea in the Late Tortonian (7.25 Ma) (Haberland et al. 2017). Since then, lacustrine and alluvial deposits accumulate in this basin until the Middle Pleistocene (~0.5 Ma) when the Guadalquivir River captured the basin (Gibert et al. 2007a). During the Plio-Pleistocene, the Baza Basin was occupied by a large lacustrine system with a central saline lake surrounded by a fringe of marginal ephemeral ponds where all archaeological and paleontological finds occur (Gibert et al. 2007b). In Orce, the most relevant archaeological sites are found in the upper 20 m of the stratigraphy, where there is a 25 m-thick lacustrine unit outcrop (Scott et al. 2007). This unit corresponds to shallow lakes that accumulate thick deposits of fine-grained carbonatic sediments that preserved the fossils until erosion uncover those layers.

The Chronology

Since its early discovery, the fauna assemblage of Venta Micena was dated as Early Pleistocene (Biharian biozone), but a numerical age was missing. The lack of volcanic material in the basin makes paleomagnetism the best technique to solve the age of the archaeological sites. A preliminary magnetostratigraphic study claimed for the identification of the Olduvai subchron in the upper 10 m of the Barranco the Orce section (Agustí et al. 1997), located only 300 m west from Barranco León. The lower boundary of Olduvai was placed at the same stratigraphic level than the BL-5 site, suggesting an age of 1.95 Ma for BL finds (Gibert et al. 1998). Later, a review of the paleomagnetic data at Barranco the Orce proved that the rocks were remagnetized in the present field direction invalidating these old chronologies (Gibert et al. 2006b). In 2000, a study of the upper part of the Barranco León and Fuente Nueva-3 sections showed only reverse polarity placing the sites in the Early Pleistocene but without given a concrete age (Oms et al. 2000). It was in 2007 when a magnetostratigraphy for the complete section outcropping in Orce was published (Scott et al. 2007); this study showed a polarity sequence of three magnetozones with a sequence of reverse-normal-reverse polarity. Different field tests were done to guarantee that this normal zone was not remagnetized. The paleontological information permitted to correlate the normal zone with Olduvai subchron (1.98–1.75 Ma) and to date with accuracy the lower part of the section at 2 Ma and produce minimum ages for the archaeological sites of 1.3 Ma for Venta Micena, 1.25 Ma for Barranco León, and 1.2 Ma for Fuente Nueva-3 (Scott et al. 2007).

In an attempt to refine the age of Orce sites, two additional techniques were used:

Amino acid racemization analysis on remains from gastropods from Venta Micena produced an average age of 983 ± 58 Ky for the site. This age

Orce: Early Pleistocene Archaeological Sites, Fig. 5 Model of dispersal. Map showing the distribution of Oldowan and Acheulian technologies during the Early Pleistocene. The presence of the oldest evidences of the African Oldowan technology and later the oldest evidences of the African Acheulian technology challenge classical view of human dispersal from Africa to Europe around the Mediterranean and suggest that the Strait of Gibraltar was a permeable barrier for humans during the Early Pleistocene. The map shows a dotted line indicating the limit of the first human dispersions; there is no evidence of human presence north of this line before 0.8 Ma. The paleogeography of the Strait of Gibraltar during a sea level fall of 120 m is also indicated; under this situation the distance between continents was reduced by 50% and some islands appeared. In Africa the oldest Oldowan is at Gona (Ethiopia, 2.6 Ma), in North Africa at the site of Ain Hanech (Algeria 1.5–1.6 Ma), in Asia at Dmanisi (Georgia, 1.7 Ma) or Riwat (Pakistan, 1.9 Ma), and in Europe at Orce at 1.25 Ma. The oldest Acheulian occurs at Konso-Gardula (Ethiopia, 1.4 Ma) or Peninj (Tanzania. 1.5 Ma), in North Africa at Thomas Quarry (Morocco at 1 Ma), in Asia at Bose (China, 0.8 Ma), and in Europe at Cueva Negra (0.9 Ma) and Solana del Zamborino (0.75 Ma), both sites in SE Iberia

was validated assuming a correct age for the site of Cullar Baza-1 of 441 ± 27 Ky obtained using the same technique (Torres et al. 1997). In 2007 a paleomagnetic study placed Cullar Baza-1 at the Brunhes-Matuyama boundary 0.78 Ma (Gibert et al. 2007a) showing a much larger error in this technique.

In recent times new attempts using combined U-series/electron spin resonance (ESR) dating method have been applied without success. In

Venta Micena, five mammal teeth were sampled. The results gave disperse ages between 1.79 + 0.30/−0.23 and 0.57 + 0.08/−0.09 Ma (Duval et al. 2011). In Barranco León and Fuente Nueva-3, nine teeth samples were analyzed. Seven samples could not be dated, and the remaining two give again non-consistent ages of 1.19 ± 0.21 Ma and 0.52 + 0.09/−0.08 Ma for FN-3 (Duval et al. 2012).

The History of the Investigations

The site of Venta Micena was discovered in 1976 during a survey led by Dr. Josep Gibert, and a second survey in 1979 identified additional fossiliferous strata in the Orce section like Barranco León, Barranco de Orce. In 1982 the first extensive excavations were developed, and after the identification of a human skull fragment at Venta Micena, more work was done between 1984 and 1986. A controversy on the Orce skull halted the excavations at Venta Micena. Between 1986 and 1994, new sites were discovered, and some worked pieces of flint and quartzite were found *in situ* at some of the beds in Barranco León and Fuente Nueva-3. In summer of 1995, the first extensive excavation at the sites of Barranco León-5 and Fuente Nueva-3 was organized by Dr. Gibert producing a large collection of tools. The finds were presented at the International Conference on Human Paleontology held at Orce in September of 1995. During this conference the participants had the opportunity to examine the sites and the finds and agreed that sites yielded very old evidences of human presence (Zihlman and Lowenstein 1996) closing the debate about the early human presence in Orce. After this conference, the "Orce man" controversy was reopened by two collaborators of Gibert who unexpectedly change their opinion about the human affinity of the Orce skull (Palmqvist 1997; Martínez-Navarro 2002; Gibert et al. 1998). Because of this new controversy, the excavations were stopped again until 1998, when a new team, that integrates these collaborators, took the control of the sites of Barranco Leon and Fuente Nueva-3. Although Dr. Gibert applied for administrative permits until his premature death in 2007, no new extensive excavations were permitted at Venta Micena until summer of 2013, when a quarry located 400 m away from Quarry-3, the richest and the only one that has supplied human remains, was reactivated. In 2017 the regional administration asked archaeologist from University of Granada to lead the research project at Orce.

The Controversy on Orce Skull

In 1982 a skull fragment with human affinities was recovered, the fossil with number VM-0, and was published and named by the news media as "Orce man." It consists of two parietals and the occipital, and its external view shows typical human anatomy. Based on its exocranial morphology, curvature, low thickness, and the *impressiones digitatae* on its endocranial face, it was concluded that VM-0 belonged to an infant around 5 years old (Fig. 1) (Gibert et al. 1983; Campillo 1989).

After the endocranial was cleaned, a small internal sagittal crest was identified. This atypical anatomical feature in humans was used by some to suggest that the fossil was not human but an equine. This rumor arrived to the press in 1984 starting a debate in the Spanish news media between supporters and rivals of the human affinity. The equine hypothesis was published finally in 1987 by two of the colleagues of Gibert who participated in the discovery (Agustí and Moyà 1987). The new classification of VM-0 was based on the presence of this atypical internal crest and a supposed *sutura coronalis* in VM-0 situated at 40 mm from lambda point. This would imply that VM-0 belonged to a being with a small brain like a horse. A detailed X-ray study proved no presence of a *sutura coronalis* in VM-0 and demonstrated that all interpretations based on the presence of a *sutura coronalis* are incorrect (Campillo et al. 2003).

The same study shows a character that proves the human affinity of VM-0: the presence of a wide *sulcus sagittalis* (9 mm), the print of the superior *sinus sagittalis*. This wide *sulcus sagittalis* drained venous blood of a big brain, like the human, but not possible in a colt whose brain size is similar to that of sheep and the *sulcus sagittalis* is much narrow (Campillo et al. 2006).

Drs. Gibert and Campillo studied a large collection of human skulls including 311 X-rays (61 infants, 73 juveniles, 177 adults) and further 735 human crania (Campillo 1989). Also 72 horse crania (2, aged 0–2 months; 6, aged 3–4 months; 15, aged 7–9 months; 49 adults) but never were able to identify an equid skull which permits an anatomical comparison with VM-0 (Gibert et al. 1998). In contrast, similar sagittal crest than the one in VM-0 was identified in humans (Campillo 1989). In 2006, the endocranial morphology of an infant skull from a Roman necropolis shows an identical internal occipital crests to that of the VM-0 fragment, confirming that such crests occur in human crania disproving all previous arguments made against the human hypothesis (Campillo et al. 2006).

In an unprecedented effort to solve the "Orce man" controversy, two different laboratories carried out independent immunological test on residual proteins extracted from these disputed fossils. Dra. Borja and Dr. Enrique García-Olivares (Univ. of Granada) detected human albumin and human immunoglobulin in all three fossils. Dr. Jerold Lowenstein (University of California, San Francisco) also detected human albumin as well as human transferring and collagen in the cranial piece (VM-0) and human albumin in VM-1960. As a further check both teams found equine albumin in specimens identified morphologically as equids, and Dr. Lowenstein identified bovine albumin in two bovine fossils (Zihlman and Lowenstein 1996; Borja et al. 1997).

The role of immunology is critical here, where the morphology is incomplete," observed Prof. Phillip Tobias (Univ. of the Witwatersrand), after close examination of the fragments. Prof. Tobias concluded that "nothing in the remaining morphology would exclude their being hominid" (Zihlman and Lowenstein 1996). In reference to the study of fossil proteins Prof. Tobias conclude, "the convergence of the two laboratories, working independently of one another, by two different methods, provides very strong evidence in support of the conclusion that all three of the bones from Venta Micena are of hominid origin" (Tobias 1998).

Organic Residue Analysis in Archaeology

Alessandra Pecci
Equip de Recerca Arqueològica i Arqueomètrica de la Universitat de Barcelona (ERAAUB), Departament de Prehistòria, Història Antiga i Arqueologia, Facultat de Geografia i Història, Universitat de Barcelona, Barcelona, Spain

Introduction

Organic residues of substances that were used in the past can survive as visible amorphous residues or trapped in the porous of archaeological materials, such as ceramic matrix or plasters. The study of these residues has relied on the possibility of identifying markers or indicators of the different substances (biomarkers) that survive through time and different postdepositional environments (Evershed 1993, 2008a).

The study of these residues that can be performed with a number of analyses, instruments, and extraction methods has provided archaeologists with interesting data on different aspects of the ancient way of life.

Historical Background

As Evershed has recently shown, a major influence in the development of the field was the emergence of a new generation of analytical chemical methodologies in the middle of the twentieth century that enabled complex environmental materials to be

studied in increasingly fine detail (Evershed 2008a). Nevertheless, it was the emergence of chromatographic methods able to achieve molecular-level resolution and recognition during the 1950s and 1960s, and in particular the development of gas chromatography (GC) coupled to mass spectrometry (MS), that allowed the real development of this field of research.

The first studies were conducted in the 1970s, being the Condamin and Formenti contribution fundamental for the development of the organic residue analysis of archaeological ceramics (Condamin et al. 1976).

After overcoming the incredulity that organic residues can survive in archaeological materials, this field of research experienced a rapid development.

It is mainly thankful to the tireless work of Richard Evershed and his group that nowadays we can really consider organic residue analysis a major field in archaeological sciences. More and more laboratories exist in Europe and in the rest of the world that perform these analyses, but none have as many publications and have faced such a wide range of themes as Bristol laboratory.

While the first analyses were mostly aimed at understanding the commodities transported in amphorae, the focus of the analyses later moved to the study of the content of cooking pots and a variety of other themes, such as linings, glues, and tars. The possibilities offered by specific techniques have provided information on the species of animals, dairy and marine products cooked in the vessels, and the origin of resins and tars. In general, during the last years the characterization of more and more numerous substances, allowed recovering information on different aspects of ancient ways of life.

In particular this was due to the use of suitable extraction and analysis methods on one side, and of the application of experimental archaeology and ethnoarchaeology to the study of chemical residues.

Key Issues

Organic residues are a complex mixture of compounds absorbed within a porous substrate that is usually not visible at naked eye. These components are too small for bacteria to penetrate and undergo weak physicochemical interactions with the ceramic matrix of the pottery vessel (Reber and Evershed 2004).

These processes protect a proportion of the absorbed residues from decay and microbial attack, preserving many of the compounds in the absorbed residue from decomposition over time (Evershed 1993). Depending on the environment in which the archaeological material was preserved, residues undergo a different degradation.

Absorbed organic residue analysis has concentrated mainly on the analysis of ceramic materials and has contributed to the identification of the ancient content of pottery and therefore its use and function.

In general, these studies have been applied in the investigation of ancient food practices, some of them being related with the early diffusion of specific foodstuff such as dairy products, maize, as well as fermented beverages, such as wine, beer, and chocolate. The data obtained have sometimes been related to major transformations in human societies, such as breeding and domestication of animals, domestication and cultivation of plants, sedentarization, and landscape use (i.e., Barnard and Eerkens 2007; Brown and Brown 2011; Regert 2011).

The study of the residues preserved in ceramics regarded more generally the alimentary practices in certain periods and the food prepared and consumed at the different sites, sometimes as part of integrated studies. Also ritual practices associated with burials have been treated (i.e., McGovern et al. 1999; Guasch-Jané et al. 2006).

More specific themes are related with the aim of establishing the use and/or function of specific archaeological materials, such as cooking pots with specific forms, *mortaria*, or *amphorae*. In particular, the study of amphorae content, which corresponded to the early stage of chemical analyses of archaeological materials (Condamin et al. 1976; Heron and Pollard 1988), has recently re-entered the landscape of the organic residue analysis demonstrating that the association between amphorae typologies and content is more complex than expected and must be treated with caution, in particular if regarded as a source

for the study of ancient Mediterranean economy (Garnier 2007; Pecci et al. 2010). Also the analyses of other ceramic vessels have provided interesting data, sometimes showing that the archaeological hypothesis on the use of ceramic vessels was not correct. The analysis of different parts of the vessels has provided information on the way of cooking in the different commodities (Evershed 2008a).

Among the compounds that more commonly are identified with the analyses of the organic residues absorbed in archaeological materials are lipids (Evershed 1993, 2008a; Regert 2011); nevertheless, also many others can be studied (Brown and Brown 2011; Barnard and Eerkens 2007; Garnier 2007; Guasch-Jané et al. 2006; Colombini and Modugno 2009).

The identification of animal origin products has been a major issue in residue analysis, being possible in establishing the species of animals that were consumed, distinguishing between adipose fat and dairy products, and identifying marine origin fats (Regert 2011); this has also allowed the discussion on animal domestication. Also vegetal fats are identified, being vegetal oils being important substances in the past. Residue analysis has confirmed that also oils different from olive oil were produced, used, and traded in ancient times (Garnier et al. 2009; Pecci et al. 2010). Other vegetables such as *Brassicaceae* and *Allium porrum* have also been identified, although with some reserve (Evershed 2008a).

Another important aspect of organic residue analysis is the characterization of amorphous materials that are found either as contents, linings, and glues of ceramic or other artifacts (stone, bone, and wood) or as bulk materials. The analysis of these materials that are usually beeswax, resins, incenses, tars, bitumen, and gums is aimed at characterizing them and identifying their source (i.e., Regert et al. 2008; Stern et al. 2008). Their analysis also sheds light on the methods of preparation of these substances and on their geographical origin, as they could also be subject to trade. These same substances can be identified and preserved in the pores of ceramic matrices. Visible residues can also be adhered to lithic tools, such as blood residues.

Residue analysis can be performed also on porous materials different from ceramics, such as the plasters of the archaeological floors of households or temples, and can be useful to identify activity areas, as the liquid or semiliquid substances produced by human activities are absorbed by the porous surfaces on which the activities are performed (Barba 2007 and his entry on "▶ Floors and Occupation Surface Analysis in Archaeology" in this encyclopedia). Nevertheless, also the plastered coatings of basins that are found in production installations can be studied to establish if they were used to produce wine, oil, or other substances (Pecci et al. 2013).

Since the beginning of chemical prospection in the 1920s, it was recognized that soils preserve the chemical signature of human activities. The analysis of samples of soil from the surface of an archaeological site can be used to suggest hypothesis on the distribution of activities at the site (Barba's entry on ▶ "Floors and Occupation Surface Analysis in Archaeology" in this encyclopedia), while the study of discarded loci can be useful to get information on the way of life of the inhabitants (Bull et al. 2003). Also changes in vegetation through time can be investigated through the analysis of organic matter in soil (van Bergen et al. 1997), and the cultivation of specific crops has been proposed (Webb et al. 2004).

Finally, the study of organic residues is also related with the conservation of materials (i.e., Mills and White 1987). It is in fact important to know their origin and degradation problems before preserving and restoring them. This area of research sometimes presents conflicts between the preservation of intact materials and their study and between their preservation for further studies and the use of modern organic polymers to consolidate and preserve the shape of the piece of art.

Analyses and Sampling

For the study of organic residues, several techniques have been applied. The choice depends on the characteristics of the materials and on the facilities available at the different laboratories. Until now, gas chromatography, (GC), gas chromatography coupled with mass spectrometry

(GC-MS), isotopic analyses (GC-C-IRMS), and pyrolysis (Py-GC-MS); high-pressure liquid chromatography (HPLC); and Fourier transformation infrared spectroscopy (FT-IR) have been the most popular, although nowadays some more have been implemented. Application of ESI and APCI has given good results, and NMR has been tested. For a first screening of the samples, also solid-phase microextraction (SPME) and other quicker methods can be used (Barnard and Eerkens 2007; Brown and Brown 2011; Colombini and Modugno 2009). Moreover, spot tests can be used both for the analysis of archaeological floors (Barba 2007) and as a first approach to the analysis of ceramic vessels. These tests do not allow identification of the specific substances that were contained in the vessels but make it possible to suggest some hypothesis on their use and discard some contents. Moreover, they could be combined with other techniques to obtain better results for the analysis of different archaeological materials (Middleton et al. 2010).

Different extraction methods have been proposed depending on the substances that are investigated and the techniques used; the total lipid extraction being the most common. Recently, several articles have been published on the possibilities of identifying wine residues in archaeological materials (Pecci et al. 2013).

As for the sampling, there is a trade-off between the quantity of sample to be analyzed and the information that can be recovered that depends on the characteristics of the samples and the techniques that can be applied (destructive versus nondestructive or micro-destructive analyses). Most of the time, especially when the residues are trapped in the matrix of ceramics and plasters, destructive analyses are carried out. An amount of sample (ranging from fractions of a gram to several grams) is crushed in order to be sure to recover information on the substances adsorbed in these matrices. Nevertheless, in specific cases, nondestructive analyses are carried out either performing the extraction without crushing the sample (i.e., with solvents directly inside an archaeological vessel) or performing microanalyses (i.e., FT-IR-LA). This is especially the case for museum objects.

As for the problem of contamination, if the materials are carefully treated after recovery, this is not common. Nevertheless, to keep a control on this phenomenon, it is important to sample the earth of the stratigraphic unit in which the ceramics or amorphous materials were found or to evaluate the differential presence of residues in several parts of the vessels.

Current Debates and Future Directions

Although organic residue analysis has been performed for several decades, there is still a lot to do, and different lines of research will have to be implemented in the future.

While radiocarbon dating is now common in archaeological projects and other archaeometrical techniques such as inorganic analysis of ceramic vessels and isotopic analyses of bones are everyday more common, the organic residue analysis of pottery is still quite rare.

Among the recent approaches to organic residue studies that deserve a special attention, the radiocarbon dating on the organic residues preserved in archaeological ceramics is particularly interesting (Berstan et al. 2008). This application will provide dates for the use of the vessels and therefore for the archaeological contexts where they come from.

Experimental DNA analyses have been applied on ceramic sherds and revealed the original contents of amphorae which had no visible physical remains (Hansson and Foley 2008). Although still in preliminary stages, the development of this kind of analyses will open a new field of molecular archaeology analyses and provide a powerful tool for obtaining information about the agricultural production, contact networks, and economies of past civilizations. The development of DNA analyses will probably change the way of performing residue analyses.

The data obtained on proteinaceous materials are also promising for the future of this kind of study, as it will provide data that can complement those obtained with lipid analyses.

As for the techniques of analysis that are already applied systematically, further investigations are

needed in the identification of the animal species with GC-C-IRMS, mainly for what concerns the data coming from regions different from Europe, with difference in C_3 and C_4 plant diffusion that can affect the results of the analyses, as well as for marine and dairy products (Regert 2011).

The recent developments suggest that new techniques each time more precise, and less destructive, will probably be available in future years.

As for the "traditional" residue analysis, until now the high costs of these time-consuming analyses and the fact that they require expensive instruments have had the consequence that they are not performed in a systematic way in archaeological projects. Nevertheless, to find a possible answer to most of the archaeological questions related to food practices and ceramic use, it will be fundamental to increase the number of samples coming from different sites and regions in the world. For instance, in order to clarify the use of specific archaeological materials such as amphorae, it will be necessary to carry out an important number of analyses and projects that involve different countries. On the other side, a diachronic study of materials coming from the same region should be performed to evaluate if important sociopolitical changes (i.e., the fall of the Roman Empire and the formation of different states in the Mediterranean area or the arrival of the Spaniards in Mesoamerica and South America) can be reflected in the food practices of the inhabitants of the region. Moreover, to use the residue analysis of pottery as markers of social relations, it will be important to look for differences among sites of the same periods and inside the same sites among different areas that can be related to different social groups. Also the analysis of materials coming from different regions in the world will be necessary to investigate ancient ways of life.

Regarding some of the issues stated above, a great limit of this kind of analyses is the difficulty in perceiving differences in the food prepared in the vessels belonging to different household, sites, or periods. Most of the time, animal and vegetal fats can be identified in the vessels analyzed, with no possibilities of pointing out major differences in the food prepared, apart from the species of animals cooked, and eventually the presence of dairy products. This fact has two implications: on one side, the right questions must be asked, taking into account all the data coming from the archaeological context; on the other side, the characterization of a bigger number of substances should be carried out. In particular, as for the question on the alimentary practices, more experiments are needed. As it has been done for oils, beeswax, wine, beer, chocolate, and a number of other substances (i.e., Evershed 2008b), foodstuffs that were typical of specific cultures should be characterized. These will be useful to recognize the changes in the alimentary practices in time and space and the influence of a culture on another one. As each cultural region has its own feeding resources, the characterization of different substances has to be done in every region.

The implementation of databases of the analyses of modern and ancient materials should be performed in order to provide a greater diffusion of the possibility of analysis and interpretation of the data and therefore increase the number of samples analyzed. Furthermore, more crossing of data among laboratories should be carried out, with the aim of the standardization of the techniques and extraction methods that can lead to the comparison among the analyses performed by different laboratories. Also the understanding of residue degradation will have to be continued, as it will allow interpreting the data of the analyses.

The study of ethnoarchaeological ceramic materials has also to be implemented for the understanding of ceramic use and residue degradation (i.e., Evershed 2008b); as ethnoarchaeological works have been carried out for the identification of activity areas in archaeological sites (Barba's entry on "▶ Floors and Occupation Surface Analysis in Archaeology" in this encyclopedia; Wells and Moreno Cortés 2010).

In general, it must be remembered that organic residue analysis is only one aspect of the global archaeological investigation that should take into account also archaeozoological, archaeobotanical studies, residues in floors, anthropological analyses, and isotopic analyses on human and animal bones, together with written sources, when they exist. The number of integrated studies should

therefore be increased to get inside such a complex world as ancient ways of life. To approach this kind of investigations, research that takes into account experiments, ethnoarchaeology, and archaeology are also to be applied.

Organization of World Heritage Cities (OWHC)

Lee Minaidis
Organization of World Heritage Cities, Québec, QC, Canada

Introduction

The Organization of World Heritage Cities (OWHC) is an international non-profit, non-governmental organization which brings together the cities from around the globe that have within their territory a site that has been inscribed on the UNESCO World Heritage List.

The OWHC was created to assist member cities to adapt and improve their conservation and management methods. In the activities of the OWHC, these cities are represented by their Mayors with the participation of their heritage management experts and technicians. Cities that are not listed as well as individuals may join the OWHC as observer members.

The OWHC has five official languages, French, English, Spanish, Arabic and Portuguese, while French, English and Spanish are the OWHC working languages.

The Mayors of the OWHC member cities form the General Assembly, the paramount authority of the Organization. At its meeting every 2 years, in the course of the World Congress, the Assembly elects eight Mayors to serve on the Board of Directors that meets at least once a year.

The headquarters of the OWHC are located in Quebec City, Canada. The General Secretariat is directed by the Secretary General, appointed by the General Assembly, who oversees the execution of mandates adopted by the governing bodies, the day-to-day administration of the Organization and personnel management. Seven Regional Secretariats support the work of the General Secretariat.

Historical Background

Following the inscription of the Historic District of Old Quebec (Canada) on the UNESCO World Heritage List in 1985, the city's Mayor, Jean Pelletier, voiced the need for World Heritage Cities to join together to face the challenges and obligations of their World Heritage status.

It was left to Mr. Pelletier's successor, Mr. Jean-Paul L'Allier, also a man of vision, to organize a meeting in Quebec City in July 1991, of 41 Mayors of listed cities to take part in the First International Symposium of World Heritage Cities. The Symposium was held under the auspices of

UNESCO with the cooperation of the Government of Canada and the authorities of the Province of Quebec.

At the end of that first symposium, the elected representatives who had attended signed the Quebec City Declaration to establish a network of World Heritage Cities. Two years later at Fez (Morocco), on 8 September 1993 the Charter of the Organization of World Heritage Cities (OWHC) was adopted by the Founding General Assembly and the decision taken that the headquarters of the Organization would be established in Quebec City, Canada.

It is remarkable that the first gathering held in Quebec City led to the establishment of an international network that includes over 230 World Heritage Cities with a combined population of over 130 million people.

Key Issues

Mission

The primary objectives of the Organization are to:

- Favor the implementation of the UNESCO World Heritage Convention
- Encourage, on both regional and international levels, co-operation and the exchange of information and expertise among historic cities on matters of conservation and management in close collaboration with other organizations pursuing similar goals
- Promote public awareness to heritage values and their protection
- Foster a sense of solidarity among its member cities

To this end, the OWHC organizes World Congresses, regional conferences, seminars and workshops dealing with the challenges to be faced in the realm of management as well as strategies pertaining to the preservation and development of historic cities.

To better articulate its goals, the OWHC has followed the example of the UNESCO World Heritage Committee which outlined its Strategic Objectives, the originally four and now five Cs (Credibility, Conservation, Capacity building, Communication and Communities), in its Budapest Declaration (2002). The OWHC has set itself five strategic directions, its own five Cs, to pursue its mission:

- Collecting experiences
- Capitalizing on know-how
- Consolidating heritage enhancement
- Constructing intercity partnerships
- Contributing to the international debate

Support

The initial grant given by the Government of Canada as well as the continued support of the Province and City of Quebec in providing grants as well as staff and premises for the General Secretariat have been crucial to the continued activities of the OWHC.

In addition to the membership fees from the cities, the Organization also benefits from the wealth of human resources that exists in its member cities. The generosity that these cities have shown in putting professional staff at the disposal of the OWHC has been a tremendous asset throughout its existence. This generosity was crucial to the creation of the seven OWHC Regional Secretariats throughout the world.

The establishment of the Regional Secretariats has been very important in the development of the OWHC, playing a significant role in achieving cohesion and unity among its member cities. The Secretariats have provided a vital link between the cities of each region and the General Secretariat in Quebec City. They facilitate the implementation of programs and projects of the OWHC, adjusting them to the cultural requirements of each region. Equally important are the activities initiated by the regions themselves, especially the Regional Conferences held every 2 years between World Congresses, which can better relate to the needs of those cities that share cultural, linguistic or geographic affinities.

The seven Regional Secretariats serve the areas of Northwestern Europe, Central and Eastern Europe, Southern Europe and the Mediterranean, Latin America, Africa and the Middle East, Euro-Asia and Asia-Pacific.

The World Congress

The OWHC has long promoted the cooperation of the various actors involved in cultural heritage conservation and management. It has been said that the OWHC is the only international platform where mayors, decision-makers and experts meet together to discuss issues of mutual concern for World Heritage Cities. This synergy of authority and expertise has yielded many positive and significant results.

As envisaged from the outset, a World Congress is held every 2 years, which the OWHC considers to be its most important event. The host city of each World Congress, elected by the members of the OWHC at the previous Congress, has the responsibility of proposing a theme and making provisions for its development and presentation in the scientific sessions.

These assemblies provide a unique forum, giving decision-makers and professionals the opportunity to share their experiences and to learn about new developments and strategies for meeting the critical challenges associated with the conservation and management of World Heritage Cities.

Mayors' Workshop

The job of a Mayor of a World Heritage City is not easy. Most Mayors are not heritage experts but the responsibility of preserving or managing historic sites becomes theirs once they are elected. Having conserved their rich heritage over time, World Heritage Cities hold the keys to understanding long-term evolution of a place from the past and on to the future. City governments are at the heart of the action. As guardians of the world's heritage, World Heritage Cities face an additional challenge – any action taken at these iconic places can attract considerable attention and influence the adoption of good management practices elsewhere.

To assist the local authorities in their difficult task, from 2005, the OWHC has introduced at its World Congresses a Mayors' Workshop as a conference session, focusing on the experiences of the host city with the inclusion of site visits. These workshops, organized in collaboration with the Getty Conservation Institute, aim to raise the awareness and to enhance the sensitivity of Mayors regarding heritage issues as well as to give greater insight into the methodology of protecting and managing historic resources in their cities.

The Jean-Paul L'Allier Heritage Prize

The Jean-Paul L'Allier Heritage Prize is awarded by the OWHC, at the end of a competition and selection process, to one of its member cities that has distinguished itself by its achievements in the conservation, enhancement or management of property inscribed on the World Heritage List and located within its territory. The Prize is awarded every second year at the World Congress.

Projects and Programs

Compilation of Case Studies

The OWHC project, "Compilation of Case Studies," under the leadership of our member city, Lyon, France, and in cooperation with UNESCO, the Council of Europe, the France UNESCO Convention, the Netherlands Funds in Trust, the Getty Conservation Institute and ICOMOS, aims to take advantage of the experiences of its members and prepare a lasting contribution on two major questions that managers of historic cities face:

- How to manage an urban, inhabited and living heritage site?
- How to respect the values of heritage while allowing the city to grow and develop?

The case studies submitted from the member cities have identified and presented exemplary achievements in one of the fields of heritage management and urban development such as traffic, lodging, public space, commercial or tourism functions and architectural creations. The studies will be posted on the OWHC website, www.ovpm.org and ultimately will be published, with the addition of other studies, in the form of a "how to" guide.

Youth Programs

The OWHC public awareness program places emphasis on youth as an investment in the future. Through the years the Organization has introduced projects and programs such as international drawing contests, youth forums, the twinning between schools in World Heritage Cities and an

international video production competition. All of the youth activities aim to promote an understanding of the importance of one's cultural heritage and the need to preserve it.

City2City
The longstanding City2City program facilitates the sharing of information and expertise as well as joint initiatives between member cities.

Partners
The OWHC has had the benefit of the continuous support of its partners in its activities.

From its founding, the OWHC has enjoyed a close cooperation with UNESCO and especially the World Heritage Centre, which was instrumental in its creation. This relationship was formalized with UNESCO by the signing of a Memorandum of Understanding in February 2002. The OWHC takes part in many UNESCO initiatives, including those concerning Historic Urban Landscapes. Conversely, UNESCO supports and participates in several OWHC projects.

In addition to its collaboration in the Mayors' Workshop, the Getty Conservation Institute, chose to assist three World Congress host cities in the selection and development of their themes as well as in the selection of speakers and the format of the scientific sessions. Through the years, the OWHC has also been supported in its activities by its other partners, the Council of Europe, the Getty Foundation, ICOMOS, ICCROM and the World Monuments Fund.

Future Directions

Throughout its existence, the OWHC has been a part of the crusade for the better preservation and management of World Heritage Cities, recognizing that their inevitable evolution and growth are posing ever-greater challenges to the achievement of these goals. The OWHC through its programs and in collaboration with its partners, seeks to respond to these and other issues, to achieve a balance and make a relevant, constructive and prospective contribution for the holistic, sustainable development of its member cities.

O

Orientalism: Islamic Archaeology and Its Colonial Context

Daniel Hull
Department of Archaeology, University of York, York, UK

Introduction

For most of the history of Islamic archaeology, it has been conducted overwhelmingly by non-Muslims, often from nations with a political, and sometimes an openly colonial, interest in the

regions which contained the archaeological subject matter of their choice. These parties have predominantly, especially until World War II, been from France, the USA, Germany, and Britain, with significant contributions also from Belgium, Italy, Spain, and Russia. The broader political agenda of each of these nations had an undeniable impact on the way in which survey and excavation work was carried out and indeed the conclusions which this work produced. The advent of post-processual theory in the 1980s brought critiques of the conduct of archaeologists, pointing out that archaeology has since its origin as a serious academic pursuit been to some extent a "vehicle of validation for social groups engaged (and enmeshed) in industrial growth, capital accumulation, and colonial expansion" (Hinsley 1989: 79–80). However, it is arguable that Islamic archaeology has been *particularly* susceptible to the influence of colonial thought and practice, with Islam and its influence regarded as an exotic "other," separate and distinct from the majority of those investigating it, and depicted in opposition to an apparently superior "West."

The term "colonial" can be defined in a number of ways. Trigger (1984) attempted to make a distinction between imperial and colonial archaeology, but for much of the nineteenth and earlier twentieth centuries, the relations between Western nations and the Middle East, for example, fluctuated between the two. The definition used here is a broader one, that it is "the archaeology of countries where European powers have subjected native populations to various forms of institutionalised domination" (Jones 1997: 9).

Exploitative contact by Western nations over large areas of North Africa, Western Asia (often described as the Middle East), and Central Asia took a variety of forms. Such contact has included direct military invasion and political control (as in French control over Algeria and the Russian invasion of Turkestan in the nineteenth century), sustained attempts at political control and some military intervention (as in the British and French presence in Egypt in the nineteenth and earlier twentieth centuries), the interwar "Mandate" period (where Britain and France divided much of the Middle East between themselves in the form of "protectorates" during the 1920s and 1930s), and more complex forms of intellectual representation (as in the Americans in various parts of the Middle East and Germany in the Ottoman Empire from the very end of the nineteenth century and up to World War I). These kinds of early political and military contact had a profound impact on the ways in which archaeological thought developed, an impact which has only begun to evolve away from such a colonial outlook since the 1990s but which in some ways continues.

Historical Background

Islamic archaeology came relatively late to the attentions of European and American archaeologists. Although a rise in Orientalist literature and study had begun during the early eighteenth century, it was not until the 1880s that significant research avenues and funding structures for Islamic art, architecture, and archaeology developed (Vernoit 1997: 1–2). Islamic art had been regarded by scholars for much of the nineteenth century as unaccomplished and inferior to either Classical or Christian traditions. In 1855, James Fergusson could describe Islamic architecture in such simple and dismissive terms as "a pointed arch style, without pillars or entablatures, and with a system of ornamentation peculiar to itself" (Fergusson 1847, cited in Vernoit 1997: 1). Indeed, as late as the first decade of the twentieth century, H.C. Butler, in his otherwise pioneering publication of a survey of the Limestone Massif and Hauran regions of Syria, fails to hide his disappointment that Islamic period settlement had changed and obscured the finer, more "civilized" Roman and Byzantine architecture. He comments of the village of Harran, for example, that "unfortunately it was chosen as a place for settlement by the early Moslems and was almost completely rebuilt by them" (1907: 423).

Islamic levels were often hastily excavated, with the "real" business of Classical, Iron Age and earlier remains the intended goal. This attitude continued in some areas well after World War II. In the new state of Israel, for example,

occupation levels of the Islamic period were regarded as unimportant and routinely discarded long after a serious interest in such deposits had developed in neighboring Lebanon and Syria (Silberman 1989: 232, 234).

Key Issues

The maturing of Islamic archaeology as a subject of serious academic interest during the late nineteenth century came at a significant moment in relations between the changing political entities of North Africa, the Middle East and Central Asia, the powerful nation-states of Europe, and the United States.

The effects of this changing relationship can be seen in a number of ways, but it is important to be clear that Islamic archaeology did not simply occur *within* this political context. After all, archaeological thought and practice "must be understood as *constituted*, not just shaped or influenced or interfered with, by its social, political context" (Wylie 1989: 94). This means that not only can we recognize the presence of forms of *bias* imposed by archaeology's colonial context but it is also important to understand that Islamic archaeology was profoundly interlinked with the colonial agenda in ways which had a significant effect for the operation of *both* archaeological inquiry *and* the process of acquiring and holding colonies in predominantly Islamic lands.

The nature of that interlinkage can be defined as threefold: logistical (military and diplomatic), institutional, and intellectual. Describing and understanding the colonial context of Islamic archaeology is important not merely as an academic exercise but as a method of decoding and interpreting the significant body of work produced. However, as a counterbalance, it should be stated that to deconstruct the colonial context of Islamic archaeology is not necessarily to destroy or entirely dismiss the data and publications it produced. Substantial bodies of work have been carried out which may still be useful for scholars today, but that work may become *more useful* to us if we can understand the political context within which it was produced.

Diplomatic Context

The establishment of a permanent administrative presence created both the thirst for and the possibility of explorative missions to collect information on behalf of Western governments, and archaeology was an important and attractive target for such journeys. These journeys were described as *Reisen* by German teams, *voyages* or *missions* by the French, and *expeditions* by the British and later the Americans. Travelers such as Joseph Rousseau in Syria and Iraq in 1807, Pascal Coste in Egypt and Iran in the 1820s, Charles Texier in Asia Minor and Iran during the 1830s, de Vogüé in Syria during the 1860s, and Alois Musil in Transjordan during the 1890s combined observation of physical archaeological remains with ethnography, philology, and a broader religious and political assessment of the populations encountered.

As archaeological observation and intervention became more specialist in the later nineteenth and early twentieth centuries, the links between such practitioners and the colonial administrations for whom they worked did not diminish. For example, Austen Henry Layard served as ambassador in Istanbul during the 1880s, Gertrude Bell was influential in informing the British response to the Arab Revolt and served in the British High Commission in Iraq, and J.W. Crowfoot was a member of the Egyptian civil service. A notable consequence of the presence of European administrators in the Middle East was their ability to influence antiquities legislation and infrastructure to their advantage, such as the introduction in Egypt of an antiquities policy by Auguste Mariette in 1858, the creation in the Ottoman Empire of a General Directorate for Imperial Museums in 1889, or the creation in 1920 of a Department of Antiquities in Palestine during the British Mandate.

Military Context

Military conquest was often followed closely by archaeological examination. Russian military advances in Central Asia during the late 1860s, for example, led to a number of scientific expeditions.

Following the defeat of Abdul Malik Tura, the Russians established Samarkand as the capital of the newly formed "Russian Turkestan," and the Trans-Caspian railway reached the city in 1888. Already by 1885, one of the first large-scale excavations of an Islamic city had begun there (Rogers 1974: 50–55). Archaeology can be seen as a primary tool in this context in the interpretation and "knowing" of newly acquired territories, particularly where significant differences were perceived as existing between the conquerors and the conquered.

Furthermore, the invasion and holding of ground by military means required a detailed understanding of the topography and distribution of populations through the creation of detailed mapping. Such mapping relied initially on the sketches and descriptions made by travelers and archaeologists, and as it became more sophisticated such as those records made by the Bureau Topographique du Levant during the French Mandate over Syria in the 1920s, it in turn enabled archaeologists to discover and understand archaeological sites in more detail. The aerial photography carried out in the Middle East and North Africa by British, French, and German crews during World War I also contributed a great many new sites, with the French Jesuit Priest Antoine Poidebard a particularly notable practitioner.

Institutional Context

From the 1880s, such diplomatic and military engagement in North Africa, the Middle East, and Central Asia by France, Britain, the USA, and Russia led to the establishment of more formal institutional underpinnings and the creation of the earliest true "discipline" of Islamic archaeology. This new discipline was helped substantially by the creation of a number of foreign schools and institutes throughout the Middle East, such as the British School of Archaeology in Egypt and the Institut Français de Damas. But the early formation of research agendas using such schools as their bases was (and to some extent remains today) an almost entirely foreign phenomenon, with the conception of subjects and methods of research rarely involving any meaningful input from local archaeologists (Hull 2007: 100).

The interests of the emerging discipline of Islamic archaeology were heavily influenced by art historical interest, rather than socioeconomic analysis. As the mass surveys of the first half of the twentieth century gave way to more intensive, single-site studies, the lens, and to some extent technique, through which such studies were focused was an aesthetic one. Just as colonial ambitions were driven in part by the potential for the exploitation of natural resources and trade routes, Islamic antiquities emerged in the years prior to World War I as a desirable and marketable resource. A significant market in Islamic period objects opened up from sites such as Fustat, Rayy, and Raqqa, leading to significant amounts of looting (Vernoit 1997: 5). Such an exploitative and aesthetically driven attitude toward Islamic archaeology was not confined to the black market, with Western museums also developing a great appetite for high-status Islamic artifacts and funding research projects to gather examples into their collections (see Patterson 1986: 8 for a description of the appetite of American institutions during the nineteenth and early twentieth centuries).

Similarly, Oleg Grabar's two-volume study of Qasr al-Hayr al-Sharqi described the architectural elements of the high-status structures in some detail but failed satisfactorily to explain the site's wider function and socioeconomic context, not least due to an unwillingness to examine seriously the lower-status settlement to the east of the *qasr*. Divorced of this more nuanced and informed archaeological evidence, the standing structures seem isolated and unexplained. A more recent study has analyzed more convincingly the chronology and function of the site (Genequand 2005, 2008).

Intellectual Effects

The most influential and debilitating aspect of these earlier attempts at archaeological study of the Islamic period was not logistical or institutional but intellectual. Islamic archaeology was,

until the 1990s at the earliest, still a disconnected, specialist discipline, kept at arm's length from other periods and regions. The "Orient," and in many ways Islam specifically, was viewed as something separate and distinctly different from those Western archaeologists and institutions which were carrying out the bulk of the work.

This is in large part because archaeological study of "Eastern" subject matter has tended to be regarded as "special," unique to the "East." We may reflect, for example, on Butler's description of the surface remains of the Hauran that "it represents a distinct racial, if not national life, and which is Oriental in sentiment and in expression" (Butler 1907: vi). Opinions such as this produced a lasting attitude that such remains required a special outlook in order to deal with them. The study of Islamic archaeology, architecture, and the decorative arts tended to be associated with "academic pigeonholing with. . .'exotic' archaeological studies placed away from the received mainstream and thus made to appear remote, inaccessible and different" (Insoll 1999: 3). This is reflected in the fact that studies of Islamic archaeological material often derived from university departments whose primary emphasis was on the "Orient" as a region. Admittedly, this has led to a rich cross-fertilization of ideas from different disciplines, such as anthropology, linguistics, literature, and history. However, it may also be argued that this method of study has isolated many of the narratives drawn from Islamic material from broader, interregional intellectual processes pursued in mainstream archaeology departments whose emphasis is subject, rather than area, related. For Islamic archaeology, this situation has sometimes had the consequence of limiting the application of theoretical frameworks and field methodologies developed within archaeological practices elsewhere.

Edward Said and Orientalism

This intellectual context did not form on its own – it was directly influenced, if not largely created, by the political context within which it was first formed during the early years of substantive contact between "East" and "West" in the eighteenth and nineteenth centuries. Indeed, this context can be described as evolving into what Edward Said has termed "Orientalism," whereby representations of an "East" are juxtaposed as separate from a "West" and where "the Orient came to be seen as stagnant and despotic in order to define the democratic dynamism of Europe" (Hodder 1998: 125; Said 1978). Said asserted that the motivations behind this study, the methods through which it has been conducted, and the ways and the location in which it has been presented are "a way of coming to terms with the Orient that is based on the Orient's special place in European Western experience" (Said 1978: 1). The product of this process has been, for its creators, not only an Orient which is "a place of romance, exotic beings, haunting memories and landscapes, remarkable experiences" but also "the source of its civilizations and languages, its cultural contestant. . .its contrasting image, idea, personality, experience" (1978: 1–2). In short, Said argued that an Orient had been created which was an exotic "other," set in opposition to a more dynamic, functionally superior Occident.

The studies which have resulted from this polarized approach are, according to Said, "shot through with doctrines of European superiority, various kinds of racism, imperialism, and the like" (1978: 8). But crucially, scholarly inquiry and the cultural media which derived from such work were, consciously or otherwise, products of a colonial process and were bound up within its machinery. Archaeological surveys of the kind that created the works of de Vogüé, Butler, Creswell, Sauvaget, Bell, and others were not simply *products* of the domination of certain Western nations over the "East" – they were actively involved in the business of domination. Indeed, archaeology played a role in the depiction of a hauntingly beautiful yet despotic "East" by eighteenth- and nineteenth-century Europeans, with the historic environment forming an important backdrop in such illustrations as Delacroix's *Algerian Women in their Apartments* and Léon Benett's exotic illustrations of locations such as Samarqand for the Jules Verne novels. These depictions had a strong influence over European

and American imaginings of North Africa, the Middle East, and Central Asia. Furthermore, as is described above, the exploratory work of archaeologists on the ground also played an active role in carrying out colonial policy.

Edward Said's notion of Orientalism is not without its critics, and academics from various disciplines have expressed difficulty in accepting his view (Halliday 1993; Irwin 2007). Criticisms have been expressed that Said tended to overstate his case and that his views derived from some kind of personal grudge against Western academia. He has been accused of perpetrating the very juxtaposition of representation of which he himself complained. Said did not engage directly with archaeology in his writings. Nevertheless, the theoretical framework which he provided is regarded widely within disciplines such as anthropology as useful in accounting for the nature of Orientalist studies in the past and also in striking a cautionary note in any cultural representations, particularly when the culture is not that of those doing the representing.

One of the consequences of Orientalism is that Islam has been depicted too strongly as a divisive influence in the course of history. The influential work of the Belgian historian Henri Pirenne, often called the "Pirenne thesis," was particularly significant in this regard (Pirenne 1937). For Pirenne, the Roman Empire continued largely unchanged in the Eastern Mediterranean, and so the unity of the Mediterranean Sea in cultural and economic terms remained largely intact: it was Islam that broke the economic ties which bound the Mediterranean region together, and so the social and political processes of early medieval Europe began. Just as Said has described, Pirenne was in essence using Islam to define Europe.

For the scholars who inherited this tradition of thought, Islam was also portrayed as a divisive, cultural shock. For Georges Tchalenko (1953), who spent much of the 1930s and 1940s mapping and interpreting the olive oil-driven "dead cities" of the Limestone Massif in northwest Syria, Islam swept through the lower plains, isolating these upland communities and destroying the trade routes which had enabled olive oil to flow into Mediterranean markets. According to Tchalenko, this process impoverished the 700 or so villages of the Limestone Massif and began a process of decline and abandonment. This view can be seen as the continuation of a much older intellectual framework. In fact, the arrival of Islamic thought and the spread of Arab culture have since been shown to have occurred more gradually and in subtle and different ways throughout the Middle East and the Mediterranean (for the Limestone Massif, see Sodini et al. 1980; for more general comments on the spread of Islam, see Walmsley 2007: 45–47, 111–112).

Another consequence of the Orientalist intellectual context is what might be termed "essentialism," where Islamic culture came to be thought of as consisting repeatedly of the same elements and its material culture assumed to indicate a predictable "pattern" which could be read in a relatively simple manner wherever it is encountered. Muslim society has been assumed by some to be distinct, self-contained, and unchanging. One example of this is the nature of commentary for much of the twentieth century on the Islamic city. Some have concluded that a set number of fixed elements make up a geographical "kit" unfolded by Islamic conquerors in the seventh century and which remained in place thereafter: the high-status citadel (*qasr*), a congregational mosque, *suq*s with quarters for separate trades, communal baths, closed neighborhoods for each extended family group consisting of courtyard houses, and a caravanserai outside the city walls are some of the elements typically described (e.g., von Grunebaum 1961, cited in Carver 1996). A difficulty in such an outlook is that these elements of a "typical" Islamic city are assumed – in a fashion typical of the romantic outlook of the Orientalist – to be somehow unchanging, without the dynamism and complexity assumed of Western societies.

The apparently clear, but ultimately flawed, historical and intellectual framework which Orientalist thinking established also led to the miscategorization of sites. A stark example is provided by Fergusson's misunderstanding of the Dome of the Rock as the Church of the Holy

Sepulchre later taken over by Muslims. The significant technological achievement of the Harbaqah dam in Syria was assumed to be Roman, without any strong dating evidence to justify such a claim, simply on the grounds of its solidity and sophistication (Schlumberger 1986). This site has since been more convincingly identified as Umayyad in date, feeding as it does a sophisticated mill and irrigation system at Qasr al-Hayr al-Gharbi some 17 km away (Genequand 2006: 64).

This under-recognition of early Islamic achievement created a divisive rush to identify a clear difference and to assign this difference (even if unspeakingly) as ethnically or racially derived. Such a division seemed somehow to "fit" and to make sense to those seeking to explain the complex social and political changes of the fourth to ninth centuries. Hugh Kennedy wrote an influential piece in 1985 which sought to capture the essence of changes from Byzantine to early Islamic society in the Middle East. In "From Polis to Medina," he concludes that the wide, ordered streets of the Classical Eastern Mediterranean became in the early Islamic period cluttered, winding alleyways focused wholly on commerce at the expense of a calm and ordered urban landscape. There is almost an inference here of helpless, chaotic collapse, as "broad, colonnaded streets were invaded and divided up by intrusive structures, both houses and shops, and became more like narrow winding lanes than the majestic thoroughfares of classical antiquity; and the extensive, open agora, scene for markets and meetings, was gone" (Kennedy 1985: 4–5). Such changes also coincided with a switch away from carts toward pack animals, again Pirenne's theme of a turning inward toward the great Syrian Desert and away from the Mediterranean markets of the Roman period.

Kennedy is careful to note that some of these changes occurred earlier than the arrival of Islam, and he warns us against issuing value judgments. However, at the same time, there is a continuity of thought in Kennedy's conclusions which extends half a century back to some of Jean Sauvaget's analysis of Islamic cities in the 1920s. It was always difficult with such works to avoid the implication that the arrival of dark and winding streets somehow derived from the encroachment of a winding, deviant Oriental mind. This may not explicitly have been the intention of authors in all cases, but the insinuation could be read nonetheless. More recently, the conduct of more sophisticated urban archaeological projects with greatly improved chronologies has led many to react against the model of Classical streets becoming clogged and neglected by Islamic *suqs*. Cities like Jarash, for example, have been shown to be far from the "putrid urban skeleton left behind after the decay of a once respectable 'Roman' metropolis" in the early Islamic period, with the maintenance, enhancement, and adaptation of the municipal infrastructure of the city an ongoing priority well into the seventh and eighth centuries (Walmsley 2007: 84).

Future Directions

It has taken some time for this context of thought to change. The period following World War II was one of significant self-definition for newly formed nation-states in the Middle East, many of which established new national museums and antiquities services and developed a keen appetite for Islamic period remains to inform an emerging national identity. Such processes have been more recent in North Africa, and more recent still in Central Asia, but it remains a fact that in all of these regions, Islamic archaeology is still predominantly (though no longer exclusively) practiced by scholars from elsewhere (there are exceptions, such as Hawker et al. 2005). Until the 1990s, the research agenda employed for Islamic archaeology remained those defined prior to World War II: essentially art historical, set by Western Orientalists, and continuing to define Islam as a decisive break with the past and a divisive influence on the Mediterranean and wider region. Theoretically, practitioners of Islamic archaeology took little notice of the changes and self-reflexive thinking brought about in other archaeological disciplines from the late 1960s. Methodologically too,

excavation of Islamic sites has continued to suffer from the widespread exploitation of large, cheap, local labor forces, with projects sometimes poorly supervised and with little meaningful knowledge exchange between local archaeologists and their European and American "partners."

Over the last 30 years, there has been a gradual evolution in the relationship between Islamic archaeology and the European and American writers who are still, largely, its creators. A significant reappraisal of the impact of Islam has occurred, particularly regarding its role during late antiquity, with an emphasis now on more subtle and nuanced changes occurring in different ways in different areas. Walmsley has concluded that "while there were significant changes, overall urban life continued strongly in early Islamic Syria-Palestine" and that social changes probably did not occur to any great degree until somewhat later in the ninth century (2007: 112). The macro-social model of a widespread and sudden impact from the 630s, conceived in the later nineteenth century and continued by influential scholars like Pirenne, has been contradicted by the collection of data of a higher quality deriving from research agendas conceived within more reflexive intellectual frameworks.

Islamic material culture is now more frequently treated as the archaeological record of faith and its sociopolitical context, rather than a historical "moment" exclusive to the Middle East (Insoll 1999 is an important text in this regard). Thus, there has been a diversification of interest to Indonesia, sub-Saharan Africa, India, and indeed Western Europe.

But it is clear that the relationship between Western academia and Islamic archaeology has far from completed its evolution. We must continue to be wary of the academic exclusion of the Muslim voice; secondly, there continues to be a complex and largely unequal political relationship between those regions of the world where Islam predominates and the "West." This inequality arguably continues to lead those who play a role in representing Islam – whether scholars, journalists, or others – to continue the long tradition of overemphasizing the difference and the disconnection between Islam and others and thus failing to see some of the complex comparisons and interrelationships which certainly exist today and which archaeology can elucidate for us in the past.

And new and substantial challenges have emerged. For example, it is difficult to be sure whether the highly destructive influence of the so-called Islamic State in Iraq and al-Sham, or *Daesh*, can be considered colonial or not, but it is certainly the case that group this used archaeology in the active business of domination. Many archaeological sites, and indeed archaeologists, have been caught up in the violence in Syria, Iraq, Libya, and elsewhere, but, more than this, explicitly Islamic archaeological symbols have been damaged in order to generate publicity and to punish local populations (Harmanşah 2015). The destruction of the monastery of Dayr Mar Elian al-Sharqi, visited frequently by both Christians and Muslims within the local community, and the Great Mosque of al-Nuri in Mosul, have been cast as active players, their destruction a powerful tool used to represent a political outlook by *Daesh*, sometimes broadcast without critique by Western media.

Orientalizing Phenomenon: Greek Archaeology Perspective

James Whitley
Mediterranean Archaeology, Cardiff University, Cardiff, UK

Introduction and Definition

The Orientalizing in Greek Archaeology is something that, at first sight, looks straightforward but on closer examination becomes anything but. Traditionally, the term Orientalizing refers to a phase in Greek history when Greeks adopted a number of ideas, motifs, and technologies from the Near East and Egypt. It also corresponds to an archaeological phase within the Early Iron Age (c. 1,100–700 BCE) or Archaic (c. 700–480 BCE), usually dated to the seventh century BCE (c. 700–600). It has also come to mean a style, particularly a style of painted pottery that employs a large number of motifs or images that conspicuously display their Near Eastern or Egyptian origin. The palmette, the "tree of life," the lion, and the griffin all count as "Orientalizing" motifs. They can all be traced back to prototypes (usually to be found in metalwork) in art from the Levant (modern Syria, Palestine, Lebanon) or Egypt.

An example of this style of painted pottery is the Orientalizing of Knossos in Crete, dating to the seventh century BCE (Brock 1957; Moignard 1996, 1998). This polychrome pithos (no. 993, from tomb II in the Fortetsa cemetery near Knossos; Brock 1957: 92) illustrates many of these features traditionally taken to be "Oriental." On its central band, it has a guilloche, a cable motif which must derive from some metal prototype; on its lower belly, it has a lotus chain, again a motif common in the art of both Egypt and the Levant. The debt to Eastern prototypes is clear.

That the Orientalizing was both a style and a phase, and was confined to the seventh century, used to be one of the fixed points in the main evolutionary sequence of Greek Archaeology. Over the past three decades, however, this picture has been shattered. First, Walter Burkert redefined the Orientalizing, not as a style or a phase, but as a revolution that affected all aspects of Greek culture, both literary and material (Burkert 1992; cf. West 1997). The adoption of Oriental motifs on painted pottery was, therefore, linked to the borrowing of ideas and stories from the Levant and their incorporation into the corpus of Greek storytelling. Then Martin Bernal mounted his critique of what he saw as the "Aryan" tendencies within traditional classical scholarship (Bernal 1991). In insisting on the uniqueness of the Greek achievement, traditional scholarship necessarily downplayed Greece's debt to the Near East and Egypt (or so he argued). Sarah Morris (1992) took this argument further. For her, there was never really an Orientalizing phase. Greece was always in the process of "Orientalizing," from the Bronze Age down to the conquest of the Achaemenid (Persian) empire by Alexander the Great. Contact with, and borrowing from, the Near East was the norm rather than the exception.

The Orientalizing then can be defined in a number of ways: first, as a *phase*, confined to the seventh century, and then as a *style*, one that adopted motifs to be found on Oriental metalwork and applied them to the surface of painted pots. Neither of these definitions is very satisfactory if we want to consider the full range of the cultural encounters between the Near East and the Orient. It is perhaps best to consider the Orientalizing as a *process* whereby the Greeks adopted what they found good or useful from their Near Eastern neighbors. Or rather, it was an aspect of a wider process by which the Mediterranean world (the Greeks, the "Orientals," and various Italian peoples) became highly interconnected, especially but not exclusively during the eighth and seventh centuries BCE (Horden and Purcell 2000). There is as yet no widely accepted term for this process. However we define it, the Orientalizing remains an encounter between "the Greeks" and "the Orient." Do these categories withstand any external scrutiny?

Key Issues

Greeks and the Orient

Bernal was right about one thing: we owe to Classical scholars our commonsense notions not only of what Greek but also Oriental culture was. Greek culture is the community of Greek speakers, whose collective identity (or national consciousness) is expressed equally in its literature, philosophy, art, and material culture. But this picture does not in fact withstand any close scholarly scrutiny. It is, for example, extremely unlikely that there was anything like a Greek national consciousness, or sense of collective identity, before the sixth century BCE (i.e., after the "Orientalizing" period; see Hall 2002). Material culture groups (archaeological cultures) do not correspond to our commonsense notions of what is Greek and what is Oriental (Gunter 2009: 50–123). Ethnic, linguistic, and material culture groups are not tightly defined cultural blocks, but overlapping, polythetic sets, with porous boundaries (see Clarke 1978: 263–266 and 311–408; cf. Whitley 2001: 231–233). Take Cyprus, an island with a mixed population of Greek speakers, Phoenicians (West Semitic speakers), and "Eteocypriots" (a supposed remnant of an aboriginal population, whose linguistic affinities are unclear). During the Iron Age in Cyprus, a Late Bronze Age style of pottery gradually and seamlessly yields to something labelled "Cypro-Geometric" which in turn yields to "Cypro-Archaic." There is no Orientalizing phase as such, because (in a sense) Cyprus is a part of the Levant and shared many cultural traits with much of Northern Syria throughout this period. Nor are the distinct groups of Greek, Phoenician, and "Eteocypriot" speakers distinguished by any particular material culture traits – the chief "Phoenician" city Kition (despite its reputation as a "Phoenician colony") looks much like any other Cypriot city in the Iron Age and Archaic periods (see Iacovou 2008).

But if "Greek" and "Oriental" are not clearly defined entities or categories, where does that leave the Orientalizing? Well, it is at least clear that the inhabitants of the Aegean did gradually transform their Geometric pottery styles into something markedly more figurative and colorful and that this process involved making creative use of metalwork that came from the Near East. It is less clear, however, that this transformation was effected entirely within the seventh century BCE. Indeed, different regions of Greece had different kinds of Orientalizing phases, which do not all fall within the seventh century. In Crete, for example, contact with points further East was never really lost. The inhabitants of Knossos continued to make use of Cypriot-inspired tripods and Egyptian-style lotus-handled jugs throughout a long period from c. 1,000–600 BCE (see Brock 1957). In the ninth century BCE, large quantities of Oriental-inspired metalwork is deposited in Knossian graves, leading some scholars (notably Boardman 1967) to argue that this period saw a guild of North Syrian metalworkers set up shop in late ninth-century Knossos. Certainly, motifs derived from Levantine metalwork form part of the inspiration for the curious "Protogeometric B" style of pottery, which some have seen as Greece's first "Orientalizing" style.

Regional Variations: Athens (Attica) and Corinth

But the same is not true of other parts of Greece in this period. In Athens, Oriental objects (a North Syrian bronze bowl) and Oriental technologies (techniques of granulation and filigree in goldwork) make their appearance in rich ninth-century graves. But there is no discernible effect on the decoration of the locally produced painted ceramic finewares (Whitley 1991: 116–137). These remain strictly Geometric in their exterior decoration. In the succeeding eighth century, there are some signs that knowledge of both the iconography and techniques of Levantine metalwork are having an effect on local craftsmen. Gold bands, decorated with embossed quadrupeds, appear in some numbers, and such animals then appear in friezes on some notable pieces of Late Geometric pottery. The famous Dipylon vase, Athens NM 804, datable to around 750 BCE, almost certainly used as a grave marker for an important female aristocrat, is decorated mainly with strictly

Geometric ornament. Such animal friezes as such vessels possess remain subsidiary to the overall Geometric design (Whitley 1991: 137–180). It is only in the middle of the seventh century that Athenian (or conceivably, Aeginetan) potters and painters adopt most of the techniques of a truly polychrome, Orientalizing style (called Middle Protoattic, or the "Black and White style"). On the Polyphemos amphora from Eleusis (see Morris 1984, Fig. 6), the cables between the panels clearly derive from metalwork, and the gorgons have heads in the shape of bronze cauldrons decorated with animal protomes (the most characteristic form of Orientalizing metalwork).

Compared to its neighbor Corinth, the Athenian Orientalizing style appears half-hearted. The full-blown Corinthian Orientalizing style is called Protocorinthian and is confined to the seventh century. But it is much more deeply engaged with Near Eastern metalwork than its contemporary Athenian style or Knossian Orientalizing styles. These styles borrowed polychromy and a range of motifs (guilloche, cable, lotus). Protocorinthian – or at least Middle Protocorinthian – borrows a metalworker's technique, engraving, and applies it to painted pottery. Engraving was used to define the features, the detail of painted figures, to remarkable effect. Take the Macmillan aryballos, a highly decorated flask used for holding perfumed oil, now to be found in the British Museum. Like the Polyphemos amphora and the pithos from Knossos, this vase shows a distinctive motif derived from Oriental metalwork; on the shoulder, there is an elaborate lotus chain (or scroll). But the vase goes further, and its debt to Oriental metalwork goes deeper. Its spout/mouth is in the form of a lion's head, and the figures and the shields of the duelling hoplites are outlined with engraving. And unlike the vases from Knossos and Eleusis, whose function (or final use) was funerary and whose decoration is correspondingly large and splashy, all the figures in the Macmillan aryballos are in miniature. The vase itself is only 7 cm tall; to see the figures in the museum, you have to look through a magnifying glass.

What is most remarkable about this most creative of the Orientalizing pottery styles of Greece is that it seems to come out of nowhere. Whereas both in Knossos and in Athens there is evidence that Oriental techniques and artifacts had been known from at least the ninth century BCE, there is little evidence for Oriental stimulus in the Corinthia before c. 700 BCE. The Late Geometric Corinthian style, while distinctive, owes nothing to the Orient, and the finds of Oriental objects (some bronze bowls called phialai) that appear to have arrived in any major Corinthian sanctuary (Perachora or Isthmia) are few. One could argue that the very unfamiliarity of Oriental material culture provided a greater stimulus and thus invited a more sophisticated response. And Protocorinthian probably remains the most influential of all the Greek Orientalizing styles of the seventh century. First perfume flasks, then pouring vessels (such as the Chigi vase, an *olpe*), and finally the whole range of shapes that came later to be associated with the Greek symposium (in particular the krater) start to turn up in various sites in Italy and not only sites of Greek colonization, but Etruscan and Latin sites as well. Orientalization is thus linked to Hellenization and to that complex of mutual borrowings and interactions characteristic of the period c. 800–600 BCE ("Mediterraneanization," Morris 2003).

The Mediterranean Perspective

It is the scale, range, and profound consequences of this process of Mediterranean transformation that might make a narrow focus on styles of Greek painted pottery appear myopic in the extreme. Certainly, there was a lot more going on than some creative borrowing of craft techniques. Oriental models affected other media, sometimes in a more or less direct copying of Levantine prototypes. So the so-called Astarte (nude female) figurines that appear all over the Aegean, but especially in Crete, in the seventh and sixth centuries BCE differ only slightly from similar examples in the Levant or the Phoenician settlements in the Western Mediterranean. And much of the best evidence for the impact of Oriental material culture comes not from graves in Greece or Italy but from major sanctuary sites. Olympia, later the greatest of Panhellenic sanctuaries, became the recipient of a number of Near Eastern engraved bowls (Markoe 1985), and, in the seventh century,

Olympia becomes the home of a number of tripod cauldrons dedicated with griffin protomes, following closely on models produced in Urartu and Assyria (which in turn provided the model for the gorgon heads on the Polyphemos amphora). Sanctuaries indeed seem to fill up with various Near Eastern "entangled objects" (sensu Thomas 1991) in the seventh and sixth centuries BCE. Oriental ivories from Nimrud and the Phoenician coast are deposited in the Idaean cave along with the "Orientalizing" bronze tympana produced by Cretan craftsmen as offerings to Cretan Zeus in the eighth and seventh centuries BCE. But the most spectacular example of this tendency to deposit Oriental antiques with extended biographies is the find Aramaean horse frontlet, securely dated by its Aramaic inscription to the ninth century BCE, in a sixth-century stratum in the sanctuary of Hera on Samos (the Samian Heraion; see Kyrieleis and Röllig 1988; discussion in Gunter 2009: 124–126).

This object then illustrates one side of the multiple and multiplying entanglements that "the Orientalizing" was connected to. Some scholars have seen more in this; engagement with Oriental (and ostentatiously Orientalizing) material culture was part of a social strategy through which elites defined themselves, in Athens and elsewhere (Whitley 1994; Morris 1999: 155–191); Orientalizing imagery on Protocorinthian perfume flasks has been considered as being intimately related to the definition of Greek masculinity (Shanks 1999). But the most long-lasting of these material entanglements does not lie with biographical objects, imagery, or art. It is the adoption of the shapes and (to a lesser extent) the phonetic values of the Phoenician script (whether or not we call it a consonantal syllabary or alphabet) and its adaptation better to suit the phonetic requirements of Greek (with the addition of signs for vowels) that marks the most creative and the most long-lasting of Greek encounters with the Levant. The adoption of the alphabet (Jeffery 1990: 1–42; Whitley 2001: 128–133) sometime in the early eighth century BCE was not merely the "recovery of literacy," as if literacy is something that can be simply discarded and then found again. It was a completely different kind of literacy and produced a completely different set of material entanglements, whose effects we can feel even today. But that is another story, one that goes beyond any consideration of the "Orientalizing" in ancient Greece.

Orquera, Luis Abel

Ramiro Javier March
CREAAH UMR 6566 du CNRS Centre de recherches en archéologie archéosciences et Histoire -INEE/SHS, Investigador del UMR 6566 CREAAH del CNRS, CNRS - Université de Rennes 1, Rennes, France

Basic Biographical Information

Luis Abel Orquera was born in Buenos Aires in 1935. His initial training was oriented toward the study of law; he graduated as a lawyer in 1963 at the Universidad de Buenos Aires (UBA). Orquera's interest in history was the reason why he decided to enroll in history while he was finishing his law studies. Then he changed History for Anthropology, and he graduated in anthropological sciences at the UBA in 1972. As a student he began his teaching career in archaeology until 1975, when the university's intervention prior to the dictatorship leaves him unemployed. He continued his teaching career in psychology teaching anthropology, and he resigned under the military dictatorship. He then continued his university career as a professor at the Universidad Nacional del Comahue until 1983 when he works for a short period at the Universidad Nacional de La PLata.

In 1985, Luis Abel Orquera entered CONICET (The National Council of Scientific and Technical Research) as an independent researcher and continued there until 2001 when he retired. In CONICET, he was a member of the advisory commissions of history, anthropology, and geography from 1988 to 1989 and of history and anthropology from 1989 to 1991. He was a member of the Argentine Society of Anthropology from 1969 to 1975, adviser of the commission of the college graduates in anthropology from 1971 to 1972, and secretary from 1972 to 1976.

Luis Abel Orquera was trained at the University of Buenos Aires, under the influence of the historical cultural school of O. Menghin, A. De Bormida, and C. Lafon. Prof. Orquera also claims, in his career, the influence of other authors such as F. Bordes, A. LeroiGourhan, R. Flannery, and L. Binford, among others. Both influences are observed progressively in his works: the French in the excavation methods and the typological classifications of artifacts and the American in the periodization and in his approach to culture that progressively leaves the culturalist criteria and adopts the evolutionary perspective and cultural ecology coming from the "new archaeology" (Orquera et al. 1977; Orquera 1987).

Major Accomplishments

Luis Abel Orquera collaborated in the drafting of several law projects aimed at regulating the exercise of the profession and archaeological heritage regulation, and he was a member of the Working Team for the drafting of the law project for the protection of the national archaeological heritage;

he was a member of the Commission that analyzed the preliminary draft of the law on defense of cultural heritage in 1984. He was an *ad honorem* advisor to the National Institute of Anthropology and Folklore from 1986 to1989.

In 1968, he received the National Fund of the Arts Award for the best grade point average in the Graduate Degree of Anthropological Sciences, and in 1986 he received the Honorary Merit Diploma in Archaeology and Cultural anthropology of the Konex Foundation.

Luis Abel Orquera is the founder of the Asociacion de Investigaciones Antropológicas (AIA). He was destined to shape the development of two generations of investigators in archaeological fieldwork and practical methodology, including the years of the dictatorship in Argentina. When democracy returned, this became the working place for CONICET scholarship researchers and researchers.

Luis Abel Orquera's regional project on the archaeology of the Beagle Channel (1975 to the present) is undoubtedly his main contribution from both a methodological and a theoretical point of view. His work on the sites of Lancha Packewaia (Orquera et al. 1977) and Tunel 1 (Orquera 1987; Orquera and Piana 1999a) contributed to the revision of theories such as the *arriconamiento* (cornering) of hunter gatherers, their primitivism, or their cultural and social inferiority inherited from the nineteenth century. His work allowed to improve the shell midden excavation techniques and to understand its formation processes (Orquera and Piana 1991). He emphasized the Beagle Channel's settlement antiquity (Orquera and Piana 1999a), and his work's archaeological richness modified the image of a static culture without major changes throughout the Holocene.

The work carried out from the concept of adaptive strategy with his colleague E.L. Piana contributed to a better understanding of the relationship between hunter-gatherers and fire-ground fishers (Orquera and Piana 2006, 2009). The relationship with the environment was deepened; the energetic relations existing with the fauna exploited by these groups and the relationship between the consumption of mollusks and mammals of the region were better understood. In the same way, his project contributed to analyze the strategies of these groups in terms of their mobility, vegetal resource exploitation, and their artistic manifestations (Orquera and Piana 1999b).

Luis Abel Orquera's innovative projects in Argentina integrated different disciplines that contributed to achieve the objectives multiplying the analytical ways to understand the significance of the different archaeological data. In 1987, his association with the research team of the Spanish CSIC and the catalan Universitat Autónoma de Barcelona gave a new impetus to his research. The Tunel VII site was the laboratory of this joint work. To Orquera, the basic idea of the project was to prove the hypothesis validity of some works according to which the ethnographic contact with Europe had modified the disposition of resources, essentially the pinnipeds, affecting the strategies adopted by the Fuegian canoers to the point of conducting them to their extinction. The contributions of this new project, and the contrast with the Marxist theoretical school, allowed to develop new approaches tending to the reconstitution of social behavior, the modes of production and reproduction of the Fuegian canoers, gender archaeology, site formation processes, and the archaeology of the European colonizers' contact period leading to a better understanding of the social transformations that occurred during this period. Finally, in the year 1999, he publishes with E.L. Piana (Orquera and Piana 1999a, b) two works of synthesis that present the results obtained in more than 20 years of research on Tierra del Fuego archaeology.

Since his retirement in 2001, he is still conducting research (e.g., Orquera and Piana 2006, 2009; Orquera et al. 2012) and contributing to the training of young researchers as Director of the Asociacion de Investigaciones Antropológicas (AIA).

Basic Biographical Information

Charles E. Orser Jr., one of the leading North American proponents of a globally aware historical archaeology of the modern world, was born in Wyandotte, Michigan, in 1950. Orser initially studied history (with minors in geology and English literature) at university, graduating from Eastern Michigan University with a B.S. in 1972. He then studied for an M.A. in Anthropology at Wayne State University, graduating in 1975. His Doctorate in Anthropology was awarded by Southern Illinois University at Carbondale in 1980; his dissertation was titled *An Archaeological and Historical Socioeconomic Analysis of Arikara Mortuary Practice*.

Orser's academic and professional career was initially focused on the Upper Midwest and Northern Plains of the United States. From 1979 to 1980, he was Assistant State Archaeologist in the Michigan History Division, Michigan Department of State. His first academic post was as Visiting Assistant Professor, Department of Sociology and Anthropology, Loyola University of Chicago (1980–1982); he then moved to the University of South Dakota, where he was Visiting Assistant Professor in the Anthropology Program (1982–1983). From 1983 to 1989, he was Assistant Professor of Anthropology, Department of Geography and Anthropology, Louisiana State University; he was granted tenure in 1988. During this time, Orser was also briefly Adjunct Faculty in the Division of Continuing Education of the University of St. Francis (Joliet, Illinois) in 1985. In 1989, he moved to Illinois State University, where he became Director of the Midwestern Archaeological Research Center. When Orser left Illinois State at the end of 2007, he had achieved the rank of Distinguished Professor of Anthropology in the Department of Sociology and Anthropology. From 2008 to 2013, he was Curator of Historical Archaeology at the New York State Museum and University of the State of New York. Since 2013 Orser has been a Research Professor at Vanderbilt University and, following a 2019 move to Canada, has concurrently been Adjunct Research Professor, University of Western Ontario, and Senior Historical Archaeologist, TMHC, London, Ontario. He is also Distinguished Professor Emeritus of Illinois State University. Orser has also held a large number of visiting positions. These include Visiting Professor, Department of Anthropology,

University of Tennessee (1988); Visiting Professor, Department of Archaeology and the Culture and Colonialism Program, National University of Ireland (1995); Visiting Professor, Department of Archaeology, University of Lund, Sweden (1996); Research Associate, Department of Anthropology, The Field Museum, Chicago (1993–2003); Adjunct Professor of the Department of Archaeology, National University of Ireland, Galway (1994–2004 and 2008–2015); Visiting Professor, Department of Archaeology, University College Dublin, Ireland (2007); and Visiting Professor, Department of Anthropology and Archaeology, University of Otago, New Zealand (2011).

Orser was a member of the Board of Directors of the Society for Historical Archaeology (SHA) between 1996 and 1998. In 2019 he was honored with SHA's J.C. Harrington Medal. This is the Society's most prestigious award and was granted in recognition of a lifetime of substantive contributions to the discipline.

Major Accomplishments

Though Orser's graduate research might have suggested a future career on the archaeology of Native Americans, his involvement in historical archaeology began before he completed his doctorate. His early publications in the field were initially focused on the Upper Midwest (e.g., Orser 1981). Over the course of the 1980s and early 1990s, however, Orser's research turned to the historical archaeology of plantations, with a particular focus on South Carolina and Georgia. This work, which culminated in the publication of *The Material Basis of the Postbellum Tenant Plantation: Historical Archaeology in the South Carolina Piedmont* (Orser 1988), served to develop many of Orser's ongoing research foci, particularly as regards race, class, status, and power and the role of material culture in the analysis of these themes. It also showed a willingness to challenge historical archaeology orthodoxies of the time, such as the use of pattern analysis in material culture interpretation (Orser 1989).

While his work continued to focus on many of the same themes, from the early to mid-1990s, Orser's attention increasingly turned to global perspectives in historical archaeology, with a particular focus on Brazil and Ireland. In his influential 1996 book *A Historical Archaeology of the Modern World*, one of the first historical archaeology volumes to argue for a coherent overtly international archaeological approach to the global nature of the modern world, Orser identified four "haunts" of historical archaeology: colonialism, Eurocentrism, capitalism, and modernity (Orser 1996: 57–58). He argued that the intersection of these themes in the fifteenth century defined both the modern world and the archaeology thereof (Orser 1996: 86). While outlining how these were relevant at both the local and the international comparative level, Orser coined what is probably his most famous maxim: "Think globally, dig locally" (Orser 1996: 183). These themes continue to inform his work (e.g. Orser 2014).

While international comparative and globally aware approaches are now much more common in historical archaeology across a range of topics, his early to mid-1990s work engaging in a theory-engaged comparative study of sites in Palmares, Brazil, and Gorttoose, Ireland, from an explicitly globalizing perspective was groundbreaking at the time. Orser's commitment to international issues in historical archaeology can also be seen in his founding of both the *International Journal of Historical Archaeology* in 1997 (he remains the editor) and the Springer book series "Contributions to Global Historical Archaeology."

While Orser continues to maintain strong research and publication links with South America, often engaging in linking transatlantic themes with South American data (e.g., Orser 2018a), the bulk of his research since the mid-1990s has focused on Ireland, where he has directed historical archaeology fieldwork in counties Roscommon, Sligo, and Donegal (e.g., Orser 2006). Much of this work has focused on Orser's familiar themes of class, status, and power (e.g., Orser 2005), usually encompassing (whether implicitly or explicitly) the globally aware approach that has characterized most of

his work since the mid-1990s. While much of his past international comparative work engages between Europe and South America, more recently he has also turned his attention to the North Atlantic (Orser 2018b). He also continues to take a strong interest in general theoretical and educational approaches to historical archaeology. His *Historical Archaeology*, currently on its third edition (Orser 2016), is one of the most widely used introductory textbooks to the subject.

Ortner, Donald J.

Mary Lucas Powell
Paleopathology Newsletter, Lexington, KY, USA

Basic Biographical Information

Donald J. Ortner (1938–2012) (Fig. 1) was born on August 23, 1938, in Stoneham, Massachusetts, the son of a conservative Christian minister, A. W. Ortner, and his wife, Marie Schweizer Ortner. Drawn to science (particularly biology) in high school, he was introduced to anthropology through the works of Margaret Mead and Ruth Benedict. His M.A. thesis at Syracuse University in 1960 was a comparative sociocultural study, but he was impressed by the courses in physical anthropology taught by Gordon Bowles. After moving to Washington, DC, with his wife Joyce Elaine Walker Ortner, a registered nurse, Ortner took a job at the National Museum of Natural History (NMNH), Smithsonian Institution, as laboratory assistant to J. Lawrence Angel. Bowles and Angel were both successful products of E. A. Hooton's program in physical anthropology at Harvard, and Ortner became intrigued by Angel's insights into the dynamic interactions between human biology and culture.

Ortner, Donald J., Fig. 1 Donald J. Ortner (2010)

Encouraged by his colleagues at NMNH, Ortner entered the Ph.D. program in anthropology at the University of Kansas to study with the skeletal biologists Ellis Kerley, Thomas McKern, and William Bass. During his year of coursework at Kansas, Ortner was awarded (co-jointly with Angel) a 5-year research grant from NIH to explore the microscopic and biochemical effect of aging on human compact bone. Ortner's dissertation, *The Effects of Aging and Disease on the Micromorphology of Human Compact Bone*, deepened his understanding of the essential biological interactions between soft tissue and bone and strengthened his conviction that a solid grounding in general human anatomy and physiology is essential for anyone seeking to conduct successful research in skeletal biology.

After his return to NMNH, Ortner was appointed assistant curator in the Department of Anthropology. At this time, Angel and two other physical anthropologists at NMNH, T. Dale Stewart and Lucille St. Hoyme, were broadening the theoretical foundations of the relatively new discipline of paleopathology (the study of health and disease in antiquity), bringing a truly anthropological perspective to this mainly descriptive field. After reading Adolph Schultz' studies of skeletal pathology in wild-shot primates, Ortner was influenced by the theoretical implications of Schultz' argument that adaptation to illness (including infectious diseases, parasites, and traumatic injuries) was a very powerful force in prehuman and human evolution. To further his education in anatomy, physiology, and the mechanisms of disease processes, Ortner enrolled in a rigorous course in orthopedic pathology taught by Lent Johnson, chief of orthopedic pathology at the

Armed Forces Institute of Pathology. This course marked a turning point in Ortner's career toward understanding the complexity of various disease processes and the web of biological and cultural factors which affected their development.

After his decision to concentrate on human skeletal remains from archaeological sites (rather on living subjects), Ortner began gaining archaeological field experience by working with colleagues at burial sites in the Washington, DC, area. He quickly acquired a broad knowledge of archaeological methods and became convinced of the importance of conducting in situ examinations of skeletal remains as well as conducting sophisticated laboratory analyses. In 1976, Ortner was promoted to curator of physical anthropology in the Department of Anthropology at NMNH (the position he held until his death in 2012), and in the following year, he joined a research project sponsored by the Smithsonian Institution (1977–1981) at the Early Bronze Age I site of Bab edh-Dhrâ, Jordan, to direct excavations of the cemeteries.

Major Accomplishments

In his long and active career, Donald J. Ortner's significant contributions to biocultural anthropology and paleopathology fall into three categories.

Teaching

Ortner organized a series of special courses on human skeletal paleopathology (1971–1974, 1985) which combined lectures on orthopedic pathology and osteology with laboratory sessions devoted to studying pathological cases from the human skeletal collections at NMNH. His stated objectives were to improve the professional competence of anthropologists in paleopathology; to foster dialogues among anthropologists, physicians with specialties in skeletal radiology and orthopedic pathology, and museum staff who curate human skeletal and mummified remains; and to develop a teaching file of photographs and x-ray films of modern, documented pathological samples and an international registry of paleopathological specimens.

Beginning in 1988, Ortner offered a similar series of short courses in paleopathology (now widely emulated at European universities and research centers) at the University of Bradford, England. From 1989 to 2010, Ortner taught a series of half-day workshops in skeletal pathology at the annual North American meetings of the Paleopathology Association. In addition, Ortner mentored numerous pre- and postdoctoral students of skeletal biology and paleopathology as well as visiting professionals from many different countries who came to Washington, DC, to study the human skeletal collections under his curation at NMNH. Through these efforts, he provided invaluable training for several generations of paleopathologists, both students and professionals.

Research in Biocultural Anthropology and Paleopathology

Ortner published 4 books and more than 100 scientific articles on various topics in skeletal biology, biocultural anthropology, and paleopathology. His most influential work in the latter field is *Identification of Pathological Conditions in Human Skeletal Remains* (Ortner and Putschar 1981; Ortner 2003). Initially coauthored with the eminent pathologist Walter G. J. Putschar, this volume presents basic concepts in human skeletal biology relevant to orthopedic pathology as well as detailed descriptions, diagnoses, and interpretations of hundreds of documented pathological examples from European museums and hospital collections. His second book, *How Humans Adapt, A Biocultural Odyssey* (Ortner 1983), presents the proceedings of an international symposium sponsored by the Smithsonian Institutions. In Ortner's contributed chapter, "Biocultural Interaction in Human Adaptation," he discusses genetic adaptations (e.g., post-childhood lactose tolerance) that have appeared in human populations in response to changing cultural contexts and other important culturally mediated dimensions of human health, such as changes in exposure to zoonoses and environmental pathogens and circumstances for the transmission of human-to-human infectious diseases.

In 1988, Ortner and his longtime colleague and friend, pathologist Arthur C. Aufderheide,

organized a symposium on human paleopathology at the 12th International Congress of Anthropological and Ethnological Sciences in Zagreb, Republic of Croatia. The edited volume of proceedings from this symposium (Ortner and Aufderheide 1991), *Human Paleopathology: Current Syntheses and Future Options*, includes brief overviews of theoretical foundations, methodologies, and cutting-edge interpretations by eminent paleopathologists on six continents. Ortner's most recent book, *The Early Bronze Age I Tombs and Burials of Bâb edh-Dhrâ, Jordan* (Ortner and Frohlich 2008), presents an exemplary biocultural analysis of the mortuary features at a major archaeological site. The detailed descriptions of the archaeological contexts of the burials are matched by rigorous analysis of the human skeletons; together, they illustrate Ortner's firm commitment to the *biocultural* perspective, in which each category of material remains yields data pertinent to their mutual interpretation. Ortner's lifelong dictum is masterfully illustrated here: that skeletal biologists should seek as much information as possible about the multiple synergistic factors (both biological and cultural) affecting human growth, development, and health in order that they may interpret accurately the specific skeletal lesions that they observe and, beyond that, the biocultural significance of disease prevalence.

Service to the Discipline of Biocultural Anthropology

In addition to his educational and research responsibilities at NMNH and his publications on biocultural anthropology, Ortner made significant contributions over the past four decades to the professional development of the Paleopathology Association (PPA), a scholarly society of physicians, pathologists, anthropologists, medical historians, and others interested in ancient health and disease. He served from 1982 to 2009 as an associate editor of the PPA's quarterly, *Paleopathology Newsletter*, and has been a member of the scientific committees for the PPA Biennial European Meetings since 1986. In 1999, Ortner was chosen to serve a 2-year term as PPA's first elected president; during his tenure, he led PPA to incorporation as a "scientific/educational" federal tax-exempt organization. In 2005, in recognition of his many years of service to PPA in diverse capacities, Ortner became the first recipient of the Eve Cockburn Service Award (named for the "founding mother" of the organization).

Note

Space does not permit the inclusion of Ortner's complete list of publications nor of his impressive roster of service activities and awards from numerous international institutions. This information appears in his curriculum vitae, available from the Department of Anthropology, NMNH, Smithsonian Institution.

Osteology Reference Collections

Douglas H. Ubelaker
National Museum of Natural History,
Smithsonian Institution, Washington, DC, USA

Introduction

The fields of bioarchaeology and human skeletal biology rely extensively on human skeletal reference collections. Although clinical studies lead to some routinely employed methodology, most techniques are based upon research conducted on reference collections curated throughout the world.

Definition

Research Collections

Collections of human remains vary considerably in their composition and documentation. Ideal reference collections are large and well preserved with accurate information about the individuals represented. Most techniques of analysis are based upon collections of known individuals with documented age at death, sex, stature, ancestry, disease history, and related life information. Many collections derived from archaeological excavations lack the type of documentation listed above but are accompanied by details of site location, culture, approximate date, and related mortuary data. All collections are of great value for research, but the type of study conducted depends highly on the representation of the individuals and the nature of the associated documentation.

Knowledge of the documentation of a collection utilized in research is critical for proper interpretation and methodology development. For example, since limb proportions vary considerably among world populations, a method to estimate living stature from long bones based on a sample of individuals from one area within the United States would be limited in its application outside of the United States. Similarly, research leading to a method of estimating adult age at death should be based on collections that have individuals with documented ages in all of the appropriate age categories. Awareness of population variation in all methodology depends upon access to collections reflecting that variability. Fortunately, well-documented collections of human remains exist globally, and new assemblages continue to be formed. Corsini et al. (2005), El-Najjar (1977), Quigley (2001), and Usher (2002) provide discussions of available collections and issues relating to their documentation and representation. Collection composition can be affected by repatriation issues and other factors. The following represents a partial global listing of key reference collections of human skeletal remains.

Examples

Brest Bone Collection: Brest, France

Skeletal and dental samples in this collection were all collected at autopsy in Brest, France, between 1996 and 1997. The collection consists of approximately 450 individuals and is located at the University Hospital (Centre Hospitalier Universitaire) in Montpellier, France (Baccino et al. 1999).

British Museum of Natural History Collections: London, England

This museum holds a large number of human remains (around 20,000), but few of these are documented. The Spitalfields Coffin Plate Collection, comprising the majority of the identified individuals at the museum, represents over 900 deceased, 387 of whose identity is known from legible coffin plates. They were buried in the crypt at Christ Church Spitalfields between 1,729 and 1,859 and excavated in the 1980s.

Name, age, and date of death are all available from the coffin plates, and additional information drawn from the historical record includes place and date of birth, nationality, place of residence,

and occupation (Cox 1989). In addition to the Spitalfields collection, approximately 106 mostly Asian crania from the nineteenth century are similarly documented. Parts of the approximately 20,000 human remains originated from different institutions and collections prior to coming to the Natural History Museum (Margaret Clegg, 2011, "personal communication").

Cape Town Documented Skeletal Collection: Cape Town, South Africa

This collection is derived from cadavers dissected in the Department of Anatomy at the University of Cape Town between 1980 and 1996. Known data include age, sex, and ancestry based on common classifications of the time (Ginter 2005). Most of the 200 individuals in the collection are over the age of 50 (Robinson and Bidmos 2009).

Chiang Mai University Skeletal Collection: Chiang Mai, Thailand

This modern Thai skeletal collection is composed of the willed remains of 104 individuals (70 males, 34 females) who were collected at the Faculty of Medicine at Chiang Mai University between 1993 and 1996 (King et al. 1998; Schmitt 2004). Documented information on this collection includes age, sex, residency, occupation, and socioeconomic range (King et al. 1998).

Coimbra Identified Skeletal Collection: Coimbra, Portugal

Excavated from the largest cemetery in Coimbra (Cemiterio da Conchada), this collection is housed at the University of Coimbra in their Museum of Anthropology. The collection includes 505 individuals, mainly of Portuguese descent, with ages from 7 to 96 years and dates of birth and death from 1826–1922 to 1904–1938, respectively (Coqueugniot and Weaver 2007). Cemetery records are available with name, sex, age, place of birth and death, date and cause of death, occupation, marital status, and parents' names (Santos and Roberts 2001; Coqueugniot and Weaver 2007).

Coimbra International Exchange Skull Collection: Coimbra, Portugal

Excavated from, and curated in, the same locations as the Coimbra Identified Skeletal Collection above, this osteological collection consists of 1,075 crania (Wasterlain et al. 2011). Both sexes are represented evenly in the collection, and the individuals are mainly Portuguese (Wasterlain and Dias 2009). All are identified from the cemetery record book with information such as age, sex, place of birth and death, year and cause of death, and occupation (Wasterlain and Dias 2009; Wasterlain et al. 2011).

Coimbra Medical School Skull Collection (Escolas Médicas I): Coimbra, Portugal

This collection was the first of the Coimbra identified osteological collections (above) to be assembled at the Museum of Anthropology at Coimbra University. The skulls were collected from medical schools in Lisbon, Coimbra, and Oporto between 1895 and 1903. There are 585 complete crania (366 male, 219 female) belonging to individuals born in Portugal or the Madeira archipelago. Birth year and death year (between 1802–1890 and 1895–1903, respectively) are documented as well as sex, age, and place of birth. The collection is mainly adult; only 2.9% (17) individuals were under 20 years old at death (Cunha and Wasterlain 2007).

Francisc J. Ranier Collection: Bucharest, Romania

First established by anatomist Francis J. Ranier in the early 1900s, the Ranier collection was separated from the Anatomy Department of the University of Bucharest in 1938, to be housed in the newly established Anthropology Institute of the Romanian Academy. Composed of crania and some postcranial elements, the collection was expanded through the 1950s, with the majority of individuals collected in the 1930s and 1940s. Remains were predominantly unclaimed individuals of low socioeconomic status recovered from nearby hospitals and morgues. Sex, age, ancestry, pathology, cause of death, and profession are available for most crania; 93% of the collection

is classified as of Romanian ethnicity, with the remainder composed of various ethnic minorities. Known age at death is primarily in the 18–60-year range, with 2,123 inventoried adult males, 1,194 adult females, and 214 children. The total count of remains is 6,800 (Ion 2011).

George Huntington Collection: Washington, DC

The Huntington Collection is composed of over 3,600 documented human skeletons housed at the National Museum of Natural History of the Smithsonian Institution. George S. Huntington of the College of Physicians and Surgeons in New York City amassed these skeletons from immigrants and US citizens who died in New York City between 1893 and 1921. The collection is very well preserved and has a high level of documentation (most individuals are of known age, sex, nationality, cause of death, and in some cases occupation), broad ethnic representation, and many examples of trauma, pathology, and occupational stress (Hunt and Spatola 2008).

Grant Collection: Toronto, Ontario

This collection was received by the Anatomy Department at the University of Toronto in the early half of the twentieth century and is now part of the Anthropology Department's research collection. Local hospitals and welfare institutions provided the majority of the 202 human skeletal remains that make up the collection, of which age at death, cause of death, sex, and name are known. Most of the individuals (175) are male, and a large number of those (147) are over 40 years old (Bedford et al. 1993).

Hamann-Todd Osteological Collection: Cleveland, Ohio

This extensive collection is housed at the Cleveland Museum of Natural History and consists of 3,300 unclaimed individuals collected by Dr. T.W. Todd at the beginning of the twentieth century (Cobb 1959). Each skeleton is associated with a file outlining basic information determined by soft tissue analysis and/or hospital and autopsy records. Data include, but are not limited to, age, sex, name, cause of death, nationality, and occupation (Andersen 1986).

Human Skeletal Reference Collection of Modern Colombian Population: National Institute of Legal Medicine and Forensic Sciences, Bogota, Colombia

This collection consists of 600 skeletons of individuals of known identity who died between 2005 and 2008. Information regarding cause of death is also available (Sanabria-Medina et al. 2016).

Institute of Normal Human Anatomy Collection: Siena, Italy

This craniological collection at the University of Siena is composed of several hundred skulls amassed between approximately 1881 and 1932. Consisting of the inhabitants of Siena and its outskirts, the majority of the skulls are of known age, sex, and state of health (Guidotti et al. 1986; Brasili-Gualandi and Gualdi-Russo 1989).

Jikei Collection: Tokyo, Japan

The skeletal remains of nearly 100 adult individuals are housed at the Jikei University School of Medicine's Department of Anatomy. The deceased lived the majority of their lives in the first half of the twentieth century (İşcan et al. 1994; Tanaka et al. 2000), and cadaver records give biographical data such as sex, date of birth and death, birthplace, and cause of death (Tanaka et al. 2000).

Johns Hopkins Fetal Collection: Cleveland, Ohio

The Johns Hopkins Fetal Collection was assembled by A.H. Schultz in the 1920s from stillbirths in the Baltimore area, while he was at Johns Hopkins University. The collection is comprised of 112 fetal and infant human skulls of known age and sex; it was moved to the Cleveland Museum of Natural History in 1973 (Erikson 1981; Ridley 2002).

Lúıs Lopes Collection: Lisbon, Portugal

Begun by Lu ́ıs Lopes in the 1980s to replace the collection of Ferraz de Macedo that was mostly destroyed by a fire, this collection (also known as the Lisbon Collection) is located at the National Museum of Natural History in Portugal. The collection currently has around 1,800 mostly

complete identified individuals, many of which came from Lisbon cemeteries and were of Portuguese nationality. Data on these individuals were drawn from cemetery records or civil registration and include age, name, sex, birthplace, occupation, address, and cause of death (Cardoso 2006; Matos and Santos 2006).

Manuel da Silva Braga Collection (MSBC): Belém, Brazil

This collection was assembled from unclaimed cadavers originating in the State of Pará, Brazil. At least 88 crania are present (Cardoso 2016).

Maxwell Museum's Documented Skeletal Collection: Albuquerque, NM

This collection is located at the Maxwell Museum of Anthropology, part of the University of New Mexico. It consists of 257 (as of 2008) mostly documented (207) individuals donated from several sources including self-donations, next-of-kin, the University of New Mexico's Anatomy Department, and the Office of the Medical Investigator. Documentation on the 207 positively identified individuals varies depending on the source of donation but generally includes population affinity, age, sex, cause of death, and donation year (Komar and Grivas 2008). Most individuals died within the last 40 years and were New Mexico residents (Yoder et al. 2001).

Modern Collection of Santiago (Colección Subactual de Santiago): Santiago, Chile

Housed at the University of Chile in the Department of Anthropology of the Faculty of Social Sciences, this collection contains around 2,000 human skeletal remains and was granted to the University from the General Cemetery (Cementerio General) in Santiago during the 1970s (Rodrigo Retamal Yermani, 2011, "personal communication"). It consists of individuals who died between 1950 and 1970 whose name, age, sex, cause of death, and occasionally date of birth and death are documented (Urzúa et al. 2008).

Modern Japanese Osteological Collection: Tokyo, Japan

This modern Japanese sample is part of an anatomical collection housed at the University Museum of the University of Tokyo. It consists of well-preserved skeletons of known age and sex from individuals who died in the late nineteenth and early twentieth centuries (Case and Heilman 2005).

Museo Nazionale di Antropologia ed Etnologia di Firenze Skull Collection: Florence, Italy

Approximately 200 individuals are represented in this documented cranial sample. The deceased are from three Italian cities (Siracusa, Catania, and Firenze), and all died at the end of the nineteenth and beginning of the twentieth centuries. Hospital dissections and local cemeteries are the sources for the skeletal material, and age at death is known from the registry office (Frederic et al. 2006; Rinaldi et al. 2006).

National Museum of Health and Medicine Skeletal Collections: Washington, DC

The skeletal collections within the Anatomical Collections at this museum are numerous. Almost 5000 specimens are included in 13 collections, 12 of which are human and 6 of which are relatively well documented including the Civil War Skeletal Collection (Sledzik and Moore-Jansen 1991; Barbian et al. 2000), Indian Wars Collection (Sledzik and Moore-Jansen 1991), Forensic Anthropology Collection, and others. These collections are all curated by the National Museum of Health and Medicine, which separated from the Armed Forces Institute of Pathology (AFIP) in 2010 and is now part of the US Army Medical Research and Materiel Command (National Museum of Health and Medicine, Skeletal Collections n.d.).

Oloriz Collection: Madrid, Spain

This collection was assembled from cadavers in the latter half of the nineteenth century (1884–1898) (Oloriz 1899; Ubelaker et al. 2009) by Federico Oloriz Aguilera and is now located in the Faculty of Medicine in the Complutense Universitaria in Madrid. The collection consists of nearly 2,000 crania of known sex, age at death, and regional origin (Ubelaker et al. 2009).

Pretoria Bone Collection: Pretoria, South Africa

This collection was created in 1942–1943 and is currently held in the Department of Anatomy at the University of Pretoria (L'Abbé et al. 2005; Robinson and Bidmos 2009). Individuals in this collection are known and are either unclaimed or donated. Age, sex, and ancestry are documented on a majority of the 704 crania, 290 full, and 541 postcranial skeletons in the collection (L'Abbé et al. 2005).

The Raymond Dart Collection: Johannesburg, South Africa

Initiated in the 1920s, this collection has grown to be one of the most extensive documented collections derived from cadavers in the world. The Dart Collection includes 2,605 individuals with known population affinities, age, and sex. The collection is located in the University of the Witwatersrand in its School of Anatomical Sciences (Dayal et al. 2009).

Robert J. Terry Anatomical Skeletal Collection: Washington, DC

The Smithsonian's National Museum of Natural History houses the 1,728 individuals which compose the Terry Collection, collected first by Robert J. Terry from 1898 to 1941 and then by Mildred Trotter until 1967. All individuals in the collection died in the St. Louis, MO area, and have a morgue record with age, sex, ancestry, date of death, as well as some additional information (Boldsen et al. 2002). Most have additional forms covering dental and bone inventory, measurements, and other records (Hunt and Albanese 2005).

Royal College of Surgeons: London, England

Collections consist of pathological specimens and those involved in studies of comparative anatomy (Surgicat:surgicat.rcseng.ac.uk).

San Nicolas Tolentino Collection: Mexico City, Mexico

In the year 2000, the Department of Physical Anthropology of the Escuela Nacional de Antropología e Historia in Mexico City began exhumation at three local cemeteries to compile a contemporary skeletal reference collection. The San Nicolas Tolentino Cemetery and the 20 de Noviembre Cemetery yielded individuals buried 7–10 years prior to exhumation, whose family members were unable to pay cemetery dues. Death certificates and other records were obtained from the Civil Registry for each of the exhumed, providing date of death, cause of death, sex, age, and occupation, as well as information related to income, quality of life, and health. Individuals exhumed from the Dolores Cemetery date to the nineteenth and early twentieth centuries with little documentation but serve as a sample to test methods verified on the San Nicolas Tolentino and 20 de Noviembre collections. The 3 combined burial populations totaled 102 individuals in the year 2006, with the goal to reach a total of 2,000 male and female individuals spanning each year of life (González et al. 2006).

Sassari Collection: Sardinia, Italy

The Sassari collection, part of the Frassetto collections of the Museum of Anthropology at the University of Bologna, Italy, is made up of 606 individuals exhumed from municipal cemeteries whose deaths date to the first half of the twentieth century. The skeletons are well preserved and have associated information on sex, age, date of death, and, in many cases, date of birth and occupation (Belcastro et al. 2008; Hens et al. 2008).

Scheuer Collection: Dundee, Scotland

The Scheuer Collection is located at the Centre for Anatomy and Human Identification at the University of Dundee. The collection has approximately 150 juvenile skeletons from predominately archaeological and anatomical contexts. Some of the individuals have documented age and sex Rissech and Black 2007; Rissech et al. 2008). The University's website provides the most current information on the collection (Center for Anatomy and Human Identification, Anatomical Collections n.d.).

Spitalfriedhof St. Johann Known Age Collection: Basel, Switzerland

The Spitalfriedhof St. Johann collection consists of 220 skeletons of known age and sex identified

through hospital and cemetery records. The Spitalfriedhof St. Johann cemetery was associated with the Bürgerspital Hospital of Basel and in use from 1845 to 1865. Over two thirds of the patients who died in the hospital were buried in the cemetery, making the collection fairly representative of the hospital mortality patterns of the time. The collection is located in the Natural History Museum in Basel (Griffin et al. 2009).

St. Bride's Church: London, England

This documented skeletal collection is housed at St. Bride's Church on Fleet Street (Black and Scheuer 1996). The 244 individuals originate from the eighteenth and nineteenth century, and coffin plates document their age and sex (Gapert et al. 2009).

St. Thomas Anglican Church: Belleville, Ontario

In 1989, a portion of the 1,564 deceased interred in St. Thomas' nineteenth-century cemetery were excavated. Of the 576 disinterred individuals, 80 were personally identified by coffin plates that were still in place (Saunders et al. 1997). The names from the coffin plates correspond with the church's burial records providing data such as age, date of death, burial date and, at times, cause of death and family relationships (Saunders et al. 1993).

Universidad de Complutense Collection: Madrid, Spain

One hundred and thirty-three Spanish adults comprise this collection, 116 of whose name, birth date (range from 1880 to 1945), death date, and cause of death are known (José Antonio Sánchez Sánchez, 2011, "personal communication"). These data were gathered from the records of the South Cemetery of Madrid, from which these individuals were exhumed in 1991 (Trancho et al. 1997). A more recent exhumation from the same cemetery has provided 86 additional individuals, 84 of which have known identity, were between 20 and 55 years of age at death, and were born between 1941 and 1976 (José Antonio Sánchez Sánchez, 2011, "personal communication").

Universidad Nacional Autónoma de México Collection: Mexico City, Mexico

Initiated in 1994, this collection is part of the Faculty of Medicine in the Physical Anthropology Laboratory at the National Autonomous University of Mexico (Molgado et al. 2007). Sex is known for all of the 172 individuals that comprise the collection, and cause of death is known for some (Socorro Báez Molgado, 2011, "personal communication").

Universitat Autònoma de Barcelona (UAB) Collection of Identified Human Skeletons: Barcelona, Spain

The UAB Collection is a well-documented, well-preserved selection of 35 Catalan adults from the twentieth century. Each individual was a Spanish national interred at the Granollers cemetery in Catalonia. The cemetery register, corresponding to each grave and gravestone, contains information such as name, age, birth and death place, cause of death, parents' names, and place of residence. This information leads to the Civil Register and birth certificates, which provide a considerable amount of additional data about each of the deceased (Rissech and Steadman 2011).

University of Athens Human Skeletal Reference Collection (The Athens Collection): Athens, Greece

This modern collection was assembled between the years of 1996 and 2003 and belongs to the Department of Animal and Human Physiology at the University of Athens. Of its 225 individuals, 214 have documented occupation, age, sex, birthplace, and cause of death based on available death certificates (Eliopoulos et al. 2007).

University of Szeged Collection: Szeged, Hungary

Located in the Department of Forensic Medicine in the Faculty of Medicine, this fetal collection contains remains from individuals with known age and sex. The age range for the collection is 4–10 lunar months (Castellana and Kósa 2001).

W. Montague Cobb Human Skeletal Collection: Washington, DC

W. Montague Cobb, anatomist and physical anthropologist at Howard University, collected and prepared the collection between 1932 and 1969 from cadavers from the anatomy dissecting room. The collection includes 700 preserved skeletons with detailed anatomical, demographic, and medical records and is located in the College of Arts and Sciences at Howard University. The Cobb collection is representative of the eastern urban population of the USA during that time (Rankin-Hill and Blakey 1994).

William F. McCormick Clavicle Collection: Knoxville, TN

The McCormick Collection, housed in the Anthropology Department at the University of Tennessee, is a documented autopsy collection of approximately 2,000 clavicle pairs collected from autopsies in East Tennessee between 1986 and 1998 (Langley-Shirley and Jantz 2010).

William M. Bass Donated Skeletal Collection: Knoxville, TN

The University of Tennessee is home to the Bass Collection, which contains a large number of modern human skeletons: over 1800 as of April 2017, and growing steadily. All skeletons are donated by family, self, or medical examiner, and therefore, identity, age, sex, ethnicity, and stature are mostly known. Age ranges from infant to adult are represented by this collection (Shirley et al. 2011).

Österreichische Gesellschaft für Mittelalterarchäologie

Claudia Theune
Department of Prehistoric and Historical Archaeology, University of Vienna, Vienna, Austria

Basic Information

The Austrian Society for Medieval Archaeology was founded in 1985. As in other countries, the importance of the archaeology of recent historical periods grew immensely during the mid-twentieth century, and a framework for scientific exchange was therefore needed. In line with this, the Society has the dual objectives of promoting research on the archaeology of the medieval and postmedieval periods in Austria and opening these fields up to interested laymen and women. Archaeological sources and their interpretation in a historical context provide the main focus for the work of the Society. Also, interdisciplinary approaches are strongly encouraged together with the collaboration with neighboring humanities and the natural sciences.

For many years, Prof. Dr. Fritz Felgenhauer and Prof. Dr. Sabine Felgenhauer-Schmiedt chaired the Society, and in this role, they have significantly influenced the direction of medieval archaeology in Austria and have helped place it in a wider European context. Currently, Prof. Dr. Claudia Theune, University of Vienna, is chairwoman of the Society; the vice-chairman is Dr. Thomas Kühtreiber, Institute of Material Culture of the Austrian Academy of Sciences; and the Society's secretaries are Dr. Gabriele Scharrer-Liska, University of Vienna, and Elfriede Huber, Vienna. Additional information is provided on the Society's website: www.univie.ac.at/oegm.

Major Impact

To achieve its goals, the Society organizes biennial international conferences at different locations in Austria. The primary regional focus of these is on the medieval and postmedieval archaeology of the entire Danube region, although studies on other European areas are also considered so as to provide a comparative perspective. Papers presented at these biennial meetings are regularly published in the journal *Beiträge zur Mittelalterarchäologie in Österreich*. The Society's other publications provide an overview of current research in Austria, and these include both edited volumes and monographs. Details of these can be found on the Society's website.

In addition to conferences, the Society organizes lectures and excursions to medieval monuments in Austria, and visits and guided tours in

museums aimed at providing members opportunities to study and learn about the archaeology of the medieval period in Austria. The Society also hosts an archive on medieval archaeology, which houses documents (including both plans and descriptions) on medieval fortifications and deserted villages in Austria and examples of a range of typical medieval ceramics.

Ostia, Archaeology of

Mary Jane Cuyler
University of Sydney, Sydney, Australia

Introduction

As the harbor city of ancient Rome, Ostia served to connect the city to the larger Mediterranean world. The colony was a major hub for traders and a port of entry for many international visitors, and therefore its structures range from the mundane but necessary granaries to lavish bath complexes. Certain architectural features of Ostia, such as the apartment building (*insula*) as a primary form of habitation, allow modern scholars to understand features of Roman life that have been otherwise buried beneath later construction.

Definition

Founded at the mouth of the Tiber River on the Tyrrhenian Sea approximately 30 km. west of Rome, Ostia was an early Roman colony. Occupied from the late fourth/early third century BCE through the late seventh century CE, today it is an archaeological park.

Key Issues/Current Debates/Future Directions/Examples

Key Issues: The Shape and Composition of the Ancient City

The cityscape is not strictly defined by the ordered grid of the "ideal" Roman colony (Fig. 1). The nucleus of the castrum, with the forum at its center and arterial roads crossing at the axis, maintains aspects of the early gridded layout of the first settlement. The area to the east of the castrum, especially to the north, was also built up in respect to the *decumanus*. The roads running from the south and west gates of the castrum veer off in different directions, possibly following very ancient paths to important locales such as the Tiber river mouth, the seashore, and salt beds.

Ostia's enormous urban scale combined with a relative lack of public urban monuments speaks to the utilitarian and commercial nature of the city. The giant *horrea* (grain storage facilities) dominate wide swaths of the city, and the numerous multistory apartment buildings and bathhouses provide ample accommodation, hygiene, and leisure for the large number of working-class people required to maintain the activities of a port city (Fig. 2). In addition to the monumental capitolium in the forum, temples and sanctuaries can be found in all regions of the city. Especially notable at Ostia is the large number of sanctuaries for the rites of the god Mithras, a deity who was especially popular among soldiers. No amphitheater has been discovered in or around Ostia, and so the theater seems to have been the primary center for entertainment.

Modern Appearance of the Excavations

The archaeological site of Ostia Antica is often compared to a palimpsest because the modern visitor can observe traces of structures from many phases of the city's 1,200-year history (Fig. 3). Two factors contribute to Ostia's multilayered appearance. First, the ancient residents of

Ostia allowed some structures, such as the theater and certain temples, to remain throughout the centuries, renovating them without destroying them. Second, archaeologists and archaeological practice have combined to dictate what is seen and not seen at Ostia, leaving exposed the remains of earlier structures at lower stratigraphic levels next to the remains of much later structures.

Foundation to Early Imperial Period

Ostia's earliest extant structure is a sturdy, rectangular fortress wall constructed on the southern bank of the Tiber River mouth. Portions of the large tuff blocks were later incorporated into other structures of the city. The early walls enclosed a relatively small area (ca. 194 x 125.7 meters) with east-west and north-south roads that crossed through gates, giving the impression of a Roman military camp or castrum. Today these roads are known, respectively, as the *decumanus maximus* and the *cardo*. This fortification of Ostia took place sometime in the late fourth or early third century BCE (Martin 1996). Around this period, other nearby coastal settlements such as Lavinium

and Ardea were also fortified, forming a defensive network along the coast (Jaia and Molinari 2011).

Archaeological evidence for Ostia's development during the third and second centuries BCE is scarce. During the wars with Carthage in the third century BCE, Rome developed into a major naval power. During this time, construction at Ostia expanded beyond the castrum walls (Mar 1991). This was due to a population increase, possibly related to Ostia's new role as the assembly base for fleets during the First Punic War and perhaps also connected to the increasing population of Rome.

Two events recorded in Livy suggest that by the end of the third century BCE, Ostia had also begun to serve as a port for receiving and distributing grain (Livy *Ab Urbe Condita* 22.37.1-6; 25.20.3). Ostia lacks a natural harbor, and grain storage facilities from this period have not survived in the archaeological record. However, geophysical survey (Heinzelmann and Martin 2002) and sedimentary cores (Goiran et al. 2014) attest to the presence of a human-made river harbor ca. 600 m west of the castrum walls. The harbor, which was deep enough to accommodate large ships, was constructed at some point during the fourth to second centuries BCE (Goiran et al. 2014).

Ostia grew primarily as a port in the second century BCE and, along with the superior harbor of Puteoli to the south, received grain from Sicily, Sardinia, and North Africa. In the first quarter of the first century BCE, there is substantial evidence for the construction of elite houses (domus) along the *decumanus maximus* west of the castrum gate. The temples in the Area Sacra, including the Temple of Hercules, were also constructed at this time. A new circuit wall was built in order to protect the newly expanded city. The earliest tombs appear outside the Porta Romana gate around 50 BCE (Heinzelmann 2000); it is unclear where Ostians buried their dead prior to this time. A single, tomb-like structure known as the "Monumento Repubblicano" located on the *decumanus* across from the theater presents a possible clue, but scholars have debated over the date of its construction (second or first century BCE?) and even its original function (Sole 2002).

At the end of the first century BCE, Ostia began to flourish under the attention of the Roman elite. Marcus Agrippa paid for the construction of a monumental theater in the first century BCE (Fig. 4). In the first decades of the Common Era, a lavish temple to Roma and Augustus was built in the center of the castrum in the area that would become the Imperial Forum. This was probably the first structure at Ostia to be fitted with marble.

The Creation of Portus

Even as Ostia grew as Rome's maritime façade, the river port was incapable of bearing the increasing burden of imports, especially the grain for the *annona* (government-controlled wheat distribution). In 42 CE, the emperor Claudius undertook the construction of an artificial harbor 4 km. north of Ostia and the Tiber.

The port encompassed an area of 69 hectares, sufficient to welcome the steady stream of merchant vessels loaded with grain and other goods from all over the world. Yet the harbor of Claudius was not completely successful. Tacitus reports that in 62 CE, a storm arose that destroyed 200 ships in the harbor (*Annales* 15.18.3). In 103 CE, Trajan constructed an internal harbor in the form of a hexagonal basin enclosing an area of 39 hectares. A series of canals connected it to the Claudian harbor, the Tiber, and the sea. These harbor facilities and the surrounding community were called Portus (Keay 2005).

Key Issues: The Architectural Revolution of the Second Century

With the harbor facilities at Portus established, Ostia began to flourish, and its population expanded significantly. This necessitated a substantial rebuilding of the city in the second century CE. We know from inscriptions that the emperor Hadrian took a particular interest in the rebuilding of Ostia, but Trajan and Antoninus Pius also funded building projects (Meiggs 1973). The primary building material of this period was fire-baked bricks, replacing the tuff blocks of the previous two centuries. Throughout much of the city, the level of the ground was raised approximately 1 m, and concrete foundations were built

Ostia, Archaeology of, Fig. 4 The theater and portico. ©Klaus Heese. All Rights Reserved

Ostia, Archaeology of, Fig. 5 Hadrianic Capitolium in the forum. ©Brent Nongbri. All Rights Reserved

to support the massive brick structures, including a monumental capitolium in the forum, multistory apartment complexes, and new grain storage facilities (Fig. 5). To ensure the safety of the grain and the city's many inhabitants, firefighters' barracks were established. A number of bath complexes were established and others renovated. Many of the famous black and white mosaics typical of Ostia were installed in this period (Fig. 6). The theater and its portico were enlarged. This "architectural revolution" obliterated large swaths of the earlier city. Much of the remains that can be seen today belong to the second century or later.

Key Issues: Third Century to Abandonment

Ostia's prosperity began to wane in the third century as Portus grew to prominence. Yet even into the fourth century, late antique homes replete with fountains, marble inlays, frescoes, and statues were built in the northwest region of Ostia

Ostia, Archaeology of, Fig. 6 Detail of a mosaic in the Baths of Neptune. ©Klaus Heese. All Rights Reserved

(Fig. 7). This flourishing of late antique architecture can be seen as opportunistic, profiting from receding spatial pressure and from the partial abandonment of parts of the city. Christian and Jewish architecture also begin to appear in this period. The Jewish synagogue was renovated with new mosaic floors in the mid-to-late fourth century (Nongbri 2015; Williams 2014), and the nearby Christian basilica, erected by Constantine I, was also renovated in the fourth and fifth centuries (Martin et al. 2002). The Goths and Vandals invaded in the fifth and sixth centuries. Although the population of the city slowly declined and structures fell into disrepair, the city was not entirely abandoned until the ninth century CE (Boin 2013).

Key Issues: The Preservation, Looting, and Excavation of Ostia

Natural forces influenced the initial preservation of Ostia and Portus. In the ninth century, the Imperial harbors silted up entirely, resulting in

malarial marshes. While the threat of malaria prevented reoccupation of the cities, both sites became a source of building material by the eleventh century, and valuable marbles were burned in lime kilns. Beginning in the fifteenth century, the sites became a source of building material for Rome, and nobility from all over Europe collected statues and inscriptions.

Meanwhile, the coastline gradually retreated westward, and a flood in 1557 altered the course of the Tiber near the site. Today, Ostia lies some 3.5 km from the seashore.

Haphazard archaeological excavations were carried out in the eighteenth and nineteenth centuries. The nineteenth century excavations contributed significantly to the Papal collections, but provenance and topography were not a priority, and few records were kept. In 1870, with the foundation of a new Italian government, Roman archaeologists such as Rodolfo Lanciani began to make records of the excavations. Regular short reports began to be published in official Italian government publications such as the *Notizie degli Scavi di Antichità*.

Dante Vaglieri, head of excavations from 1907 to 1913, systematized excavation methods. His major contribution was the establishment of meticulous documentation, a practice that subsequent directors carried out with varying degrees of commitment. Documentation came to a halt almost entirely in 1938, when Mussolini ordered extensive excavation and restoration of Ostia in preparation for a major fascist exhibition. In the years between 1938 and 1942, the excavated area of Ostia more than doubled in size, but the speed of the work prohibited more than cursory photography and documentation. This, combined with the looting and treasure hunting of the Renaissance through the nineteenth century, has resulted in massive gaps in our knowledge of Ostia for all periods. Postwar excavation and inquiries resumed the tradition of recording and photography, and scholars began to produce important volumes on aspects of Ostia's excavations, beginning with *Scavi di Ostia I: Topografia Generale* (1953).

Future Directions

Geophysical surveys carried out in the environs of Ostia demonstrate that massive areas of the city remain unexcavated. Of particular note is the vast area immediately to the south of the excavated areas. A survey completed in the 1990s revealed that this area was heavily populated with structures, including a Christian basilica and a massive villa (Martin et al. 2002). Surveys carried out immediately to the north of the Tiber in the 2000s revealed that this area also contained structures, largely unidentified. However, a clear line of a circuit wall around this northern extent of Ostia seems to match up with the line of the late Republican circuit wall to the south. This raises questions about whether Ostia's buildings occupied the north side of the Tiber in the first century BCE.

The data provided by geophysical survey do not include a chronological component; therefore small trenches excavated in specific areas of interest are necessary. This was carried out in the 1990s survey; much remains to be done in the area north of the Tiber. The analysis of core samples from drillings has also been crucial in understanding the geological conditions in which Ostia was founded and was developed.

In recent years, much archaeological enquiry has relied on the examination of archival records and the cleaning or clearing of previously excavated areas. The importance of this work cannot be overstated, as much of the excavated area of Ostia has either remained unpublished or would greatly benefit from reexamination in light of modern discoveries and with the use of new technology and typologies.

Ostia's ruins (bricks, mosaics, paintings, etc.) are constantly being altered or damaged by visitors, the climate, plant life, and modern restorations. This is difficult to prevent, and therefore a crucial task is to produce detailed descriptions and catalogues of all excavated and visible remains. A couple of blocks have been recorded in this way, but much work remains (Boersma et al. 1985; Stöger 2011).

Many thousands of graffiti scratched into the walls of Ostia remain unpublished and understudied. Thousands of stone inscriptional fragments are also unpublished and difficult to access. If Ostia is to remain a serious subject of study for current and future generations of archaeologists, these materials must be made available to scholars willing to study them and publish them in a timely manner. Similarly, the entire holdings of the photographic archive and the excavation archives must be digitized and made available online.

Ottoman Archaeology: Localizing the Imperial

Bethany J. Walker
History Department, Missouri State University, Springfield, MO, USA

Introduction

Ottoman archaeology is the youngest area of specialization within Islamic archaeology. Tied most closely to textual history and owing its nascence,

in part, to historians' investigations of Ottoman-era archival sources, the study of this ideologically charged era has been slow to capture the attention of archaeologists for a variety of reasons. Chronologically framed by the cultural-historical "golden ages" of Late Antiquity and the great empires of the Middle Ages, on the one hand, and the modern era, on the other, strata dating to the Ottoman period were once casually removed, either excavated without the same concern for detail as earlier strata or, in the worst case, bulldozed to reach levels of greater interest below. While these practices fortunately represent a bygone era of disciplinary history, underlying the general lack of scholarly interest in Ottoman archaeology before the 1990s are negative images of the era held by scholars for many years – the Ottoman era as the "Dark Ages," a period of decline and decay, centuries of devastation of landscapes, and abandonment of village life – and a general "aversion to the modern."

Ambiguities about the legal status of Ottoman-era sites have been a further deterrent to archaeological inquiry. Local departments of antiquities have traditionally relegated study of their Ottoman heritage to the realm of ethnography and legally defined the material culture of the era as "antiques" rather than "antiquities," with the preservation of period monuments falling under the jurisdiction of Ministries of Tourism. According to Jordan's 2005 Law of Urban and Architectural Heritage, for example, no structure postdating 1750 can be considered an antiquity, and the 1988 Antiquities Law No. 21 pertains only to moveable and immoveable objects made or modified before that date. Similarly, Israeli antiquities law, which also covers the West Bank, does not consider post-seventeenth-century sites and artifacts to be "archaeological."

The comparative youth of the Ottoman period (the Empire officially ending only in 1923) presents an array of challenges to practicing Ottoman archaeology that go beyond the legal. Stratigraphically, the most recent of Ottoman layers are located on the surface or in very shallow deposits below it. The tendency for Late Ottoman sites to be occupied to modern times mitigates against their excavation; modern development erases the trace of others. Furthermore, it is not uncommon for buildings constructed during the Ottoman period – sixteenth-century steam baths in Budapest and nineteenth-century farmhouses in Jordan, for example – to continue to be used or occupied. For these reasons, among others, there have been few systematic excavations of Ottoman-era sites, urban or rural. Archaeological surveys are challenged by the nature of Ottoman-era artifact assemblages, namely, the inability to identify and date the coarse wares that dominate surface collection. The nature of Ottoman-era surface finds, outside of pottery, present special problems: some of the most reliable and readily identifiable chronological markers of the period – coins and tobacco pipes (namely, *chibouk* bowls) – are picked off the ground through illicit collection and rarely make their appearance in archaeologists' survey reports. Dating rural sites is further complicated by the general paucity of coins and dated inscriptions outside urban centers.

These characteristics of Ottoman-era artifacts and sites aside the nature of the Ottoman Empire make archaeological investigations of it extremely difficult. Two centuries of extensive conquest, institutionalization of the millet system that lent autonomy to minority communities, and a move towards decentralization of the administration in the seventeenth century created a cultural, religious, ethnic, and geographical mosaic that extended across the Mediterranean. This rich diversity resulted in distinctive regionalisms expressed most strikingly in the material record and physical landscape: common wares, architectural styles, village structure, and land use differed markedly from one region to another, complicating interregional comparisons of the archaeological record. Moreover, the physical scale of the Empire means that scholars must either specialize in one small region or learn a variety of languages in order to work in different countries and access the local archives (a necessity of Ottoman archaeology today). The Ottoman Empire was as long-lived – spanning over six centuries – as it was physically vast. Over the course of this period different regions of Europe, the Mediterranean, and the Middle East came alternatively under or freed themselves from Ottoman control, their

material culture changed through adoption and adaptation in the process.

The textual resources of the period, on the other hand, present vast opportunities for socio-economic analysis of the archaeological record that is simply not available for the study of earlier Islamic societies. The Ottoman state was a bureaucratic behemoth: state ministries maintained detailed documentation on everything from taxation to garrison payrolls, creating multiple copies of the same for distribution throughout the Empire. The sheer quantity of these documents, their wide distribution, and the continued use of some of the most recent into modern times (such as registration of right to title to land) has guaranteed their preservation for contemporary study. The kinds of contemporary texts available include tax registers (*tapu defter*s), endowment documents (*vekfiye*s), fixed-price registers (*narh defter*s), Ottoman yearbooks (*salnameh*s), chronicles, garrison rolls, diplomatic documents and records of European consulates, monastic and church records and correspondence, travelers' accounts, Venetian cadastral maps, Late Ottoman-era land registers (post-Tanzimat), and memoirs. Such a vast and varied corpus of documents not only presents great potential for an enriched archaeological analysis but also requires from archaeologists responsible incorporation of textual analysis into their own research.

Definition

In the same sense that "Islamic archaeology" is not limited to the study of Muslim societies, the term Ottoman archaeology refers not to the study of a political entity but to the societies that once formed part of it. The fact that the borders of the Ottoman Empire were in constant flux for the six centuries of its existence means that what is chronologically "Ottoman" differs from one region to another. The Ottoman era for Bilād al-Shām, for example, lasted four centuries (1516–1918), whereas in Hungary, it survived a mere 150 years (1541–1699); Turkey's Ottoman heritage harkens back to the turn of the fourteenth century. Not all provinces, moreover, were equally incorporated into the Empire – many regions of Hungary and Greece, for example, remained outside Ottoman control. In spite of calls for an "archaeology of empire" (Baram and Carroll 2000: 12–13), "Ottoman archaeology" today generally denotes the study of a particular region, during the period that it was under Ottoman control.

The use of other terms to denote this chronological period reflects uniquely local perspectives on the period and regional developments in the discipline of archaeology as a whole. For example, chronologically the "postmedieval" period in European scholarship is roughly the archaeological equivalent of the historian's "Early Modern" era; the former, however, emphasizes the cultural break with the Middle Ages and general cultural and artistic decline. The Greek "post-Byzantine" era serves a similar purpose: it is a convenient term to denote the vast, anomalous period between the Golden Age of Byzantine hegemony and the birth of the Greek national state. A greater chronological precision is to be found with the "Ottoman-Turkish" era (*hódoltság kori régészet*) of Hungarian archaeologists, which is limited to the period of Ottoman occupation, and to only those regions directly controlled by the Ottoman state. An alternative to these is the "Late Islamic" nomenclature of archaeologists working in southern Bilād al-Shām. Recognizing that cultures do not routinely change with political transitions, this term roughly coincides with the European Early Modern era and includes the latter years of Mamluk and the duration of Ottoman control of the region.

Approaches to Ottoman Field Archaeology

Landscape Archaeology

The majority of large-scale, Ottoman projects adopt some kind of landscape approach. The discipline naturally lends itself to the study of the rural landscape, as continuity of settlement to modern times renders excavation difficult, and provincial textual sources of the period deal largely with land and the rural economy. There is an undeniable local focus to these projects; localized traditions in architecture, handicrafts, and

land use and tenure loom large in the survey reports. Landscape approaches are also necessarily multidisciplinary and rely heavily on textual analysis (namely, of tax registers and travelers' accounts), oral history, and geographical methods. Archaeological surveys in the Troodos Mountains of central Cyprus have adopted a landscape approach, combined with relevant textual analysis, identifying a range of different rural sites and human activities within the landscape in the process (Given et al. 2003). Likewise, in consultation with Venetian and Ottoman archives, intensive surface survey in the Pylos region of southwestern Greece has produced a social-economic map of the region for the late seventeenth and early eighteenth centuries (Zarinebaf et al. 2005; Davis and Davies 2007).

Landscape projects such as these rely heavily on Ottoman tax registers (*tapu defterleri*), which describe a fiscal landscape, however idealized, for the region. In combination with archaeological survey, the registers can be guides to reconstructing a peopled landscape of the period, with its great variety of settlement and land use types. The *defter*s, for example, account for settlements of different scale and function, as well as "non-settlements," such as the *mazra'ah*s (cultivated lands with no associated settlement, or seasonal settlements) and sites referred to as *khali* ("empty," or abandoned, villages) in southern Syria. The specialized terminology used in these and other Ottoman records suggests a refined understanding of the rural landscape and rural society by officialdom; archaeologists, however, have yet to fully tap these sources in interpreting the physical and functional variety of the landscapes they survey. Locating and investigating abandoned villages and tracing the movements of migrant minority groups, which are growing concerns of Ottoman landscape projects, are two areas of inquiry that have benefited from reference to such archival sources (Grivaud 1998; Sutton 2000; Davis and Davies 2007).

Increasingly such landscape projects have been turning to environmental history as a mode of inquiry about agricultural history, climate change, and landscape transformation. In an effort to better understand the pressures on villages that create the settlement cycles suggested by the archaeological record, environmental-oriented projects include extensive textual research and geomorphological and paleobotanical analyses as core components of their research structure. The Troodos Archaeological and Environmental Survey Project, to cite one example, makes use of archaeological survey data on landscape and textual data on landholding to investigate the development of social organization in the Cypriot countryside during the centuries of Ottoman hegemony there (Given and Hadjianastasis 2010). The commercialization of agriculture in Cyprus in the eighteenth and nineteenth centuries created new landed elites, spatially impacted village structure, changed consumption patterns, and transformed land use in ways that have correlates in the archaeological record. What constitutes a rural "community" in this period is expressed in surprising variety across the Cypriot landscape.

Questions about settlement cycles and landscape transformation inform environmental projects in Jordan as well. The Northern Jordan Project is a case in point. Launched in 2003 originally to investigate the phenomenon of settlement decline in the Late Islamic period in a regionally comparative fashion, the project has aggressively mined archival sources and broadened its base of environmental analysis to explore the dialectical relationships among settlement, land use, and environmental change (Walker et al. 2007). Ottoman-era archaeological research throughout Jordan, Israel, and the West Bank continues to focus on the ways the Ottoman state transformed the rural landscape and agricultural and pastoral communities of the region.

Historical Archaeology

Because of the wealth and diversity of documentary sources of the period, Ottoman archaeology is progressively becoming a text-based discipline. Increasingly more regional projects, in particular, have included on-staff professional historians with the language skills and expertise to penetrate the textual sources housed in the Ottoman archives. Ottoman archival sources most relevant to archaeologists relate to land use and agricultural and pastoral productivity (in tax and

Tanzimat-era property registers), settlement longevity and population migration (in tax registers and censuses), and the function of castles (in military rolls and ration records). Among the themes explored in hybrid textual-archaeological research are the emergence of new landed elites and the spatial world they create (Given and Hadjianastasis 2010); the physical transformation of the rural landscape by imperial policies (Davis and Davies 2007; Walker et al. 2007); the daily lives of Janissaries (Gerelyes and Kovács 2003; Hinds and Sakkout 1986; Hinds and Ménage 1991; Yenişehirlioğlu 2005: 260–261); local histories of settlement, land use, and toponymy (Zarinebaf et al. 2005); demography, migration, and the spatial variation in settlement by minorities (Davis and Davies 2007: 5); and disappearing villages and "fluid landscapes" (Grivaud 1998; Sutton 2000).

Imperial Archaeology

Given the distinctive regionalisms in culture, governance, and land use throughout the Ottoman territories, it is natural that the discipline of Ottoman archaeology has tended towards provincial specializations. In an effort to rise above the conceptual and operational divides separating specialists of the Balkans, Anatolia, and the Arab world, an imperial approach has developed, linking "local and imperial histories in dynamic relationships" (Baram and Carroll 2000: 12). The Ottoman Empire was one of the world's great empires and, as such, readily participated in global trade and markets, was impacted by such international phenomena as epidemics and disease control, and was transformed by large-scale migration and the new modes of transportation that facilitated it. The imperial approach is phenomenological and process oriented and encourages a multidisciplinary, cross-cultural perspective. Related to this approach are frontier studies that, by incorporating historical and anthropological methods, examine the dialectical and ever-changing relationships between local society and the state; consumption studies describing the material cultures and practices associated with newly introduced commodities, such as tobacco, coffee, tea, and fruit drinks (Baram and Carroll 2000; Gabrieli 2004; François 2008); interregional and comparative ceramic analyses documenting the distribution of export wares and local production and exchange of common wares (Walker 2009); and studies of the political economies and food systems of local societies transformed through incorporation into the Empire (Baram and Carroll 2000; Gabrieli 2004).

Historical Background

European Mainland

Hungary

Located in the heart of Europe, large parts of today's Hungary came under Ottoman control with the fall of Buda in 1541, the Ottomans ceding this territory a century and a half later with the signing of the Treaty of Karlowitz in 1699. Hungary provides a special perspective on the Ottoman era, as it formed at this time the Ottomans' western frontier – the border constantly in flux – and the state alternatively exercising authority in some regions of Hungary through garrisons of Janissaries or granting autonomy to others. The material culture of "Ottoman-Turkish" sites in the country reflects this diversity. The demographic landscape was, moreover, markedly transformed, with the emptying out of the plains (the *puszta*) and creation of "mega villages" (*mezővárosok*), as peasants fled Ottoman forces and clustered on larger, self-defending settlements; the imposition of the *devşirme* to recruit Janissaries from local villages; and the migrations of entire ethnic groups in and out of the region, the direct and indirect results of Ottoman settlement and military policies.

Hungarian archaeology has the longest history of excavations of Ottoman sites, and the country has some of the best and most diverse collections of Ottoman artifacts of the former Empire. It also has some of the best preservation of architectural remains outside Anatolia, the result of government policies to preserve and restore these monuments. The study of Ottoman archaeology in Hungary has its roots in written descriptions and

drawings of Ottoman architecture in the seventeenth century, immediately following the withdrawal of Ottoman forces. In the late nineteenth and early twentieth centuries, attempts to preserve monuments in Pécs and Buda led to salvage projects yielding important material evidence and chronological data. It was not until the interwar era, however, that a scholarly discipline emerged, under the influence of local ethnography and a growing interest in the applied arts. Fieldwork at Gazikasim Paşa Cami in Pécs was among the earliest of the systematic excavations; the excavation of rural, Ottoman-era settlements was driven by the search for the historical roots of traditional peasant houses and reflected the populist leanings of many scholars, writers, and artists of the 1920s and 1930s. The preoccupation with monument preservation that characterizes Ottoman archaeology through eastern-central Europe and the Balkans continued unabated through the 1970s: by 1975, 710 Ottoman structures had been recorded and registered, and these in a wide variety of forms: mosques, madrasas, schools, caravanserais, steam and thermal baths (Fig. 1), gunpowder magazines, forts, cemeteries, and tekkes (Gerelyes and Kovács 2003: 8). Such inventories preserved information about many structures that had since been demolished.

The questions asked of the archaeological record by Hungarian Ottoman specialists since the 1970s are largely informed by nationalist concerns. The phenomena of "disappearing villages" and internal migration have become research objectives in themselves, with research projects designed to identify ethnic groups in the archaeological record; distinguish "traditional" Hungarian material culture; and locate the settlements "lost" during the Ottoman wars and determine when they were abandoned, with recourse to the Ottoman *defter*s. Among the most notable in these regards are the excavations of the "lost" villages of Szentkirály in the southern Great Plain and market towns (*oppidum*s) Ete and Babócsa (with its cemetery) in southern Transdanubia, study of the Vlach coarse wares from the Békató graves, and analysis of the seventeenth-century Battonya jewelry hoard. In an effort to better understand the ways the Ottomans came to physically dominate the land, excavations have also focused on the castles of Szigetvár, Esztergom, and Visegrád, as well as the numerous palisades and their barracks (studied in conjunction with the military pay rolls

Ottoman Archaeology: Localizing the Imperial, Fig. 1 Király fürdő (Ottoman *hammam*) in Budapest, Hungary, sixteenth century

preserved in Ottoman archives), through which the hinterland was subdued.

Greece

Much of Greece came under Ottoman rule in the mid-fifteenth century and, with the exception of a brief period of Venetian control of southern Greece during the 1680s and 1690s, remained an Ottoman province until the 1821 War of Independence. Changes in land use and tenure and population migrations left traces on the Greek landscape; these "footprints" of Ottoman policy have become a focus of many regional archaeological projects in the country since the 1990s. Such projects have stood out for their systematic incorporation of archival studies into their larger research plans. The pioneering project in this regard was Cambridge's Boeotia Project, launched in the late 1970s, which has established high standards for studying settlement history in conjunction with documentary sources. The Ottoman tax registers and cadastral surveys have been invaluable in this regard for many subsequent projects in documenting settlement trends and describing the agricultural economy on a regional scale (Zarinebaf et al. 2005; Davis and Davies 2007: 5). The Ottoman *defter*s have provided a chronological anchor for the changes in settlement and land use suggested by archaeological surveys, and they have been an invaluable resource for the landscape and historical-based approaches described earlier in this entry.

Eastern Mediterranean

Cyprus

Cyprus passed from Venetian to Ottoman control in 1517 and remained under Ottoman suzerainty until 1878, when the island was "rented" to Britain under the terms of the Treaty of Berlin (Fig. 2). The seventeenth and eighteenth centuries witnessed important changes in local land use and demographics, with the establishment of *çiftlik*s, through land reclamation and requisitioning of land from indebted farmers; numerous tax rebellions; and a demonstrable drop in population. A century later, the large landed estates in Cyprus were producing wheat for export to Europe and Turkey, creating scarcities of the same commodity at home.

Interest in the physical correlates of these trends has guided the development of Ottoman archaeology in Cyprus. Regional surveys since the 1990s have been concerned with identifying the ways in which the Cypriot landscape was transformed by three centuries of Ottoman rule

and to distinguish medieval from postmedieval occupation, an objective hindered by the nature of postmedieval coarse wares. The first of these, the Sydney Cyprus Survey Project, which was in the field from 1992 to 1997, was designed to document landscape development in the northern Troodos from the medieval through modern periods. Its research design was a sophisticated one and set high standards for future surveys, combining traditional archaeological techniques with soil science, archival research, geobotanical and archaeometallurgical analyses, architectural surveys, and ethnography into a common GIS-based database (Given et al. 2003). Following its lead, the Troodos Archaeological and Environmental Survey Project investigated settlement, land use, and resource exploitation in the Ottoman era in the northern Troodos foothills from 2000 to 2004 (Fig. 3). This project has been most effective at identifying a wide range of rural sites and human activities in the Cypriot countryside as well as documenting the seasonal and long-term movements of peoples in that landscape (Given and Hadjianastasis 2010). More recently, the French project "La constitution des paysages dans l'Orient médiévales" has applied a multidisciplinary survey and excavation design to a single site and its hinterland – Potamia-Agios Sozomenos – documenting changes in settlement and land use at this former manor house from the medieval to Ottoman transition. It is one of the few projects in Cyprus to incorporate textual analysis with excavation of a site of the later historical periods (Lécuyer et al. 2003).

Turkey

Anatolia was the homeland of the Ottoman sultans, Osman I having established there a state in 1299 that would survive for over six centuries. As Ottoman history in Anatolia differs from the other regions of the Empire, the development of Ottoman archaeology here has also followed a different trajectory, guided by the challenges of early excavations of urban sites (Athenian Agora, Corinth, Byzantine Great Palace in Istanbul, Sardis, and Ephesus), a focus on ceramic analysis, and a ready appreciation for and application of "defterology" (the study of the Ottoman tax registers, largely located in Turkish archives). In Turkey today, the emphasis of Ottoman archaeology remains the excavation of urban and industrial sites, in an effort to better date and understand the distribution of locally produced pottery.

Interest in Ottoman sites in Turkey has remained rather limited and has been focused largely on ceramic chronology. The generally poor stratigraphy of urban sites, such as Saraçhane in Istanbul, and paucity of coins made reliance on the dating capacity of Ottoman fine wares that much more important (Hayes 1992). The

Ottoman-era sites that have been excavated since the 1980s have been largely salvage projects (Saraçhane) or targeted explorations of industrial sites (the Iznik, Eyüp, and Takfur palace kilns; Demirköy foundry). Excavations at Karacahisar fortress and of the town of Bilecik are among the few systematic and long-term investigations of nonurban, nonindustrial sites (Yenişehirlioğlu 2005: 254–260).

The Arab World

The Mamluk Empire, which encompassed much of the Eastern Mediterranean and Red Sea coast since the mid-thirteenth century, fell to Ottoman forces during campaigns in Syria in 1516 and Egypt in 1517. For the next 500 years, these Arab lands comprised the eastern frontier of the Ottoman Empire. In the sixteenth century, the state built fortresses along the *hajj* route from Damascus to Mecca, manned these forts with standing garrisons, and instituted a taxation system, in Bilād al-Shām largely based on Mamluk precedents, which systematized the incorporation of towns, villages, and Bedouin tribes into the state structure. Ottoman rule in its Arab lands, however, was inconsistent, and the strategic role of the eastern frontier quickly faded by the seventeenth century, when its forces were needed on other fronts. Much administration fell to local dignitaries and tax farmers, many of the garrison forces were removed, and the state was unable to (or uninterested in) collecting taxes from large parts of southern Bilād al-Shām until the Tanzimat reforms of the late nineteenth century. The region of Transjordan, for example, maintained its autonomy, free from the presence of tax collectors or governmental officials of any form, for a good two centuries.

The kinds of Ottoman archaeology that have emerged in the modern countries carved out of this territory reflect these inconsistencies of Ottoman rule. In today's Syria, systematic archaeological exploration of the country's Ottoman heritage is best illustrated by the excavations of the two important symbols of Ottoman rule: the Damascus and Aleppo citadels. While the Damascus excavations have revealed a continuous stratigraphic record, allowing for construction of a ceramic chronological sequence spanning the medieval through Ottoman periods (François 2008), those in Aleppo have focused on the remains of house foundations dating to the seventeenth century, a period for which domestic architecture in the Levant is poorly known (Yenişehirlioğlu 2005: 263).

Interest in the highly politicized Ottoman period in Israel and the West Bank has evolved from salvage excavations, in the first case, and cultural heritage management, in the latter. The result has been a growing appreciation for the "local" in material culture and daily life as reflected in the archaeological record of this period. Excavations at Tell el-Hesi in the 1970s and 1980s marked a turning point in the archaeology of the region; the publications of this work have become a model for the excavation and publication of late historical burials and have generated interest in traditional burial practices (Eakins 1993). The increasing number of, largely salvage, excavations of rural sites by the Israel Antiquities Authority has expanded our knowledge about village society. Palestinian excavations at Ti'innik, Zir'in, and Tell Birzeit, largely in publication stage, have been informative about settlement history and the material culture of traditional Palestinian society during the transition to Ottoman rule.

Ottoman archaeology in Jordan is the most developed of all the former Arab territories. The overwhelming rural character of the country, its autonomy from the Ottoman state for much of this period, and a proven commitment to historic preservation among government authorities and domestic and foreign archaeologists are converging factors in the ways archaeological research on Ottoman Jordan has developed. Scholarly investigations of Ottoman Jordan have followed four different trajectories since the 1980s: studies of vernacular architecture, combining architectural, archaeological, and ethnographic approaches; investigations on traditional village structure and foodways; excavations of Ottoman garrisons and *hajj* forts; and multidisciplinary regional projects documenting long-term cycles in settlement expansion and abatement and corresponding changes in agriculture. Long-term excavations at

Ottoman Archaeology: Localizing the Imperial, Fig. 4 Historic village of Saham, Jordan with turn-of-the-twentieth-century farmhouses and caves used for occupation in the Late Ottoman period, Northern Jordan Project

Khirbet Faris, Tall Hisban, and Umm al-Jimal have focused on the Ottoman period at different points in their project history; the Northern Jordan Project, described above, was designed from the start to study village life during the late medieval and Ottoman periods on a regional level (Fig. 4).

Archaeological efforts in Egypt have been strikingly different. Outside of urban revitalization projects in the traditional neighborhood known as "Islamic Cairo," with its concentration of Ottoman-era grandee houses, mosques, madrasas, and fountains, and, of course, Muhammad Ali's constructions in the Cairo Citadel, specifically "Ottoman" projects in Egypt, are rare. The most important excavation of an Ottoman site in the country is that of Qasr Ibrim, the Nile garrison south of Aswan that served the Ottoman state from 1560 to 1812. This has been a very important project, as it was the first detailed study of a Janissary garrison (here housing Bosnian troops) and systematically incorporated local documentary analysis. Unlike archaeological projects in other countries that have made use of the archives of Istanbul and Ankara, this one has relied on its well-preserved collection of Turkish and Arabic texts, retrieved on site from the excavations, that describe in detail daily life in the garrison (Hinds and Sakkout 1986; Hinds and Ménage 1991).

Key Issues/Current Debates

The identification and chronology of local wares remain the greatest challenge to Ottoman archaeology. The study of Ottoman fine wares has been pivotal in dating local pottery in associated strata. Long-term American excavations in Greece – namely, that of the Athenian Agora during the 1930s and of Corinth during the 1960s – were seminal in raising an awareness of Ottoman export wares (Frantz 1942; MacKay 1967). More recent excavations in the Anatolian heartland have refined the chronology of the most widely distributed of them (Hayes 1992). Local coarse wares, which are the most common physical remnants of the period, have only recently become a focus of study on their own, and with the restricted production and distribution of glazed wares in many parts of the Ottoman Empire, the coarse wares are frequently the only evidence of settlement in the countryside. The result has been that in many regions of the former Empire, archaeological surveys have underestimated the extent of settlement of the period and exaggerated the degree of settlement decline, as Ottoman-era sites have been misidentified as medieval. The red-bodied coarse wares of Cyprus and the so-called Handmade Geometrically Painted Ware (HMGP) of southern Bilād al-Shām are the most problematic in this regard, as their production extends well into the twentieth century (Fig. 5; Gabrieli 2004; Walker 2009).

International Perspectives

Ever mindful of the legacy of the Ottoman Empire in living societies, the practice of Ottoman archaeology in the United States today tends towards a

Ottoman Archaeology: Localizing the Imperial, Fig. 5 HMGP juglet from excavations at Tall Hisban, Jordan, Field M, sixteenth-century domestic context

practical application of scholarship to local development and sustainability. This has led to such initiatives as Project Rainkeep (http://www.rainkeep.org/) and community-oriented efforts such as the Hisban Cultural Association (an NGO) and the Dhiban Excavation and Development and Umm al-Jimal Projects in Jordan; the shared heritage project at Akko in Israel; and the Islamic Cairo Historical Development Project in Egypt (associated with the American Research Center in Egypt). Multidisciplinary projects such as these are applauded locally for their commitment to community engagement and concern for economic and agricultural development.

Future Directions

For the archaeology of the Ottoman era to progress, more systematic excavations are needed. The refining of local ceramic typologies will be impossible without their retrieval from well-stratified, and datable, deposits. The ongoing commitment to regional, landscape projects is commendable and should continue, working the occasional excavation into what are essentially survey designs. The archaeologically informed textual analysis that has emerged in recent years is one of the most promising trends in fieldwork and should become a regular component of every archaeological project concerned with the later historical periods. A rigorous investigation of written sources does not mean the return to a disciplinary past, when texts determined archaeological strategies and scope. It offers, instead, new ways to understand patterns read in the archaeological record and opens new venues of inquiry in such poorly understood aspects of premodern Islamic society as pastoralism, technology, ecology, identity, and migration.

Ottoman Empire: Historical Archaeology

Andrew Petersen
School of Archaeology, History and Anthropology, University of Wales Trinity Saint David, Ceredigion, UK

Introduction

The geographical scope and chronological span of the Ottoman Empire was huge (Fig. 1), making any assessment of its archaeology extremely challenging both because of its empirical complexity and because of the enduring political significance of its legacy. Throughout large parts of the Middle East, the Balkans and North Africa governments are still dealing with territorial, cultural, and legal issues dating back to the rule of the Ottoman sultans. In some cases such as the Israel/Palestine conflict, disputes arising out of the dissolution of the empire continue to have a worldwide impact.

Before discussing the historiography, current scope and future developments of Ottoman archaeology, it is worth briefly reviewing the accepted chronology and dimensions of the empire. The origins of the Ottoman dynasty date back to the thirteenth-century Anatolia, and Osman (?- c. 1324), its founding leader, is first mentioned in written sources from the year 1301. The fledgling Ottoman state was one of a number of small Turkic states which had established themselves between the Byzantine Empire in Western Anatolia and the Mongol Ilkhanids in the east.

Ottoman Empire: Historical Archaeology, Fig. 1 Map showing geographical extent of the Ottoman Empire during the sixteenth and seventeenth centuries (A. Petersen)

During the 1300s the descendants of Osman began to build a state in the vicinity of Iznik in northwestern Anatolia, and the first archaeological evidence of this is a coin minted in the name of Osman's son Orhan (c. 1324–1362) and dated to 1326/7 (Finkel 2005: 7). Three important features of the Ottoman state can be detected even at this early stage: one is their relationship with the Byzantines, the second is their Turkic identity, and the third is their Muslim faith. During the 1300s and early 1400s, the Ottomans gradually increased their territory which extended on to both the Anatolian and Balkan sides of present day Turkey thereby encircling the Byzantine capital of Constantinople. In 1453 the Ottomans finally captured Constantinople, effectively ending its role for more than 1000 years as capital of the Eastern Roman Empire. In the following 500 years, Turkish rule was extended over much of the area of the former Byzantine Empire, and it is probable that the Ottoman rulers were conscious of this as they developed their own imperial vision. At its greatest extent in the sixteenth and seventeenth centuries, the Ottoman Empire extended over most of North Africa (with the exception of Morocco), the Balkans, most of the Black Sea littoral, Anatolia, Greater Syria (Bilad al-Sham), Mesopotamia, Arabia, and parts of Western Iran.

The other key component of Ottoman identity was their Turkic identity. Like the Seljuks the Ottomans traced their roots back to Turkish tribes in Central Asia, and this remained a consistent feature of their culture expressed through Turkish language and customs. Although this provided the Ottomans with a secure identity, it meant that in many of their territories and particularly in the Arab provinces they were often regarded as foreigners.

The third consistent feature of Ottoman rule was the adherence to Sunni Islam as seen in the fact that Osman had a Muslim name. Although Ottoman Islam was suffused with Sufism and ancient Turkic customs which some found distasteful, it was nevertheless Sunni and enabled the sultans to pose as leaders of the Islamic world. This role as paramount Muslim rulers was expressed both when the empire was at its most powerful when Sultan Selim I (r. 1512–1520) assumed the title of caliph and in the nineteenth century when Sultan 'Abd al-Hamid II (1876–1909) sought to revive his fortunes by styling himself as a leader of Pan-Islamism against the dominant imperial powers of Western Europe.

While the beginnings of the Ottoman Empire are shrouded in mystery, the date of the end of the empire is also unclear with a variety of dates suggested including 1922, the abolition of the Sultanate; 1923, the declaration of the Turkish Republic; 1924, the abolition of the caliphate; or 1927, the year Ataturk made his great speech defining the foundations of the modern Turkish state.

Definition

Based on this rough historical outline, it is clear that the archaeology of the Ottoman Empire lies at the intersection of several branches of mainstream archaeology which include historical archaeology, Islamic archaeology, and conflict archaeology, as well as archaeology of particular regions and countries.

The archaeology of Ottoman remains is often subsumed within Islamic archaeology which in recent decades has expanded to become a significant field within the discipline. As a field of enquiry, Islamic archaeology certainly encompasses much of the material considered by archaeologists of the Ottoman Empire – this is particularly the case for sites in the Middle East where there is a strong Muslim presence and continuity from earlier periods. However, there are some parts of Ottoman territory such as the Balkans where the Muslims were in a minority and the Islamic perspective may be less helpful. A more significant objection is that the phrase "Islamic archaeology" has several theoretical problems concerning the use of the term Islamic which in recent years has become more contentious (e.g., Is Islamic archaeology an Islamic view of the past? Can a non-Muslim study Islamic archaeology? Can non-Muslims be included within the study of Islamic archaeology?). While the term Islamic archaeology continues to grow and retains a certain currency, because of the large numbers of non-Muslims within the Ottoman Empire and because the empire operated on a worldwide scale Ottoman archaeology perhaps fits better within the remit of historical archaeology.

With its emphasis on the postmedieval world and global interactions, historical archaeology is perhaps the most suitable perspective for viewing the material remains from the Ottoman lands. In particular historical archaeology emphasizes how the Ottoman world was transformed by exchanges with the New World (e.g., tobacco and coffee, see below). Also implicit in the term historical archaeology is that it deals with societies for which there is written evidence and the Ottoman territories were extensively documented even though the full potential of that documentation is only gradually being realized by archaeologists (for a recent example of the integration of texts and archaeology, see Zarinbaf et al. 2005). Ottoman written sources include imperial and local tax registers, imperial directives, local *waqf* (charitable trusts), and court records. In addition there are a wealth of narrative accounts both Ottoman and from European travelers to the region. At this point it is worth mentioning Evliya Çelebi who traveled throughout the Ottoman Empire and wrote detailed descriptions of thousands of places. His work is indispensable to many archaeologists and is frequently used as a starting point for investigations even though on occasions he is prone to exaggeration. Another figure of major importance is the Ottoman cartographer and navigator Piri Reis (1470–1513) who mapped the Ottoman world and possibly the Americas and hence

provides an insight to the Ottoman conception of the world. Historical archaeology also places an emphasis on imperialism and the application of ideologies over large areas. However, there are some limitations to this perspective, the most obvious of which is that the early years of the Ottoman Empire, certainly up to the fall of Constantinople in 1453, are more relevant to the concerns of medieval archaeology with the focus on the decline of the Byzantine Empire and the emergence of medieval principalities. Also on a practical level the archaeology of Ottoman levels at a particular site is often carried out by archaeologists interested in medieval and earlier periods with an emphasis on continuity of community. Within this context Ottoman archaeology can be considered as part of local, national, or regional archaeology. One particularly apt regional classification is Mediterranean archaeology which emphasizes the continuity with the ancient world and the interconnections between various peoples both within and outside the territory of the Ottoman Empire.

Although there are a large number of archaeological projects which in some way include Ottoman material remains as well as a large body of articles discussing archaeological material from the Ottoman period, there are few books which focus exclusively on Ottoman Archaeology. The first attempt at an overview of the subject was Uzi Baram and Lynda Caroll's recent book with the citation (Baram and Caroll 2000). This comprises a series of articles by different authors dealing with sites and monuments ranging from Anatolia to the Red Sea. In addition, the book includes an introduction and conclusion which together make a case for an "Ottoman archaeology." The other major contribution to Ottoman archaeology is the publication of a British Academy Symposium on Ottoman frontiers edited by Andrew Peacock (2009). Although not specifically devoted to archaeology, the majority of chapters are based on archaeological fieldwork and research. Together these two books provide an excellent introduction to the scope and interest of Ottoman archaeology though a theoretically informed overview is still awaited. For the present, a number of themes or potential directions of research are suggested followed by an introduction to the regional concerns of Ottoman archaeology.

Key Issues/Current Debates

Obviously the archaeology of the vast area that comprised the Ottoman Empire is likely to encompass many diverse areas of interest. In particular the position of the Ottoman Empire between Europe, Africa, and Asia demonstrates the immense complexity and potential for the exchange of people, ideas, and cultures all of which can be investigated through archaeology. Out of this, three research themes have been selected partly because they represent areas of research already underway and partly because they indicate ways in which the Ottoman Empire has influenced the present.

Coffee and Tobacco

The consumption of coffee and tobacco are one of the defining features of the modern world, and both are intimately connected with the economic and social life of the Ottoman Empire. The origins of coffee within the Ottoman Empire (i.e., highlands of southwest Arabia and the Horn of Africa) mark it as a global commodity first exploited within the Islamic world and later introduced as a crop to a variety of locations including the Americas, Africa, and Southeast Asia. Tobacco on the other hand originated in the New World and was first imported and later cultivated as a crop in the Middle East. The history of both commodities illustrates the extent to which the Ottoman Empire was an integral part of world systems. In archaeological terms both commodities can be identified from excavations and surveys in the form of ceramic coffee cups and clay tobacco pipes and are often used as a defining feature of Ottoman period assemblages. Beyond their immediate economic significance (pilgrims traveling to Mecca could pay for their travels and make a profit by buying coffee in Mecca and selling it on their return home), both coffee and tobacco had immense social implications such as stimulating

political debate and promoting more relaxed ideas about hedonism and pleasure (Grehan 2006: 1353).

Architecture

Architecture is one of defining features of the Ottoman Empire; from mosques, fortresses, and caravanserais, the stamp of the Ottoman regime is unmistakable. For example, one of the most recognizable features of an Ottoman city is the presence of a domed mosque with pencillike slender minarets. A number of important studies of Middle Eastern cities testify the extent to which the Ottomans used architecture to imprint their vision of the world throughout the empire (e.g., Weber 2009). In art historical terms Ottoman architecture is one of the few non-western traditions to be fully incorporated into the study of historical architecture (Goodwin 1978). Much of the focus in Ottoman architecture has been on Sinan who designed many of the buildings for Sultan Süleyman the Magnificent and his successors in the sixteenth century. While Sinan's genius is well recognized, the work of later architects is now also beginning to be appreciated. As well as the famous Ottoman monuments, humbler buildings such as those lining the Hajj (pilgrimage) routes to Mecca were also of a surprisingly high standard both in terms of construction and design (e.g., Petersen 2012). In contrast to the Ottoman government structures, local buildings were generally built in the local tradition though there could be some influence from the imperial architecture. One of the challenges of Ottoman archaeology is to identify the interplay of local traditions and identity against the background of the Empire (e.g., Carlton and Rushworth 2009).

Landscapes

Because the Ottoman period is relatively recent, there has often been an assumption that the landscape and environment were much the same as today. However, increasingly archaeological projects have begun to look at the evolution of landscapes during the period (e.g., Given 2000). In Palestine, for example, it is clear that the Ottomans actively promoted settlement in the countryside (Fig. 2), both to increase their revenue base and also to secure the region against nomadic incursions and agricultural degradation. In Greece the Ottomans created agricultural estates (*çiftliks*) sometimes protected by walls and armed troops to provide a secure food source for the rulers (Zarinbaf et al. 2005). In addition to the newly introduced crops such as tobacco, cotton, and maize, the Ottoman period saw the introduction of the prickly pear cactus (*opuntia*) which was used both as a defensive barrier as well as a means of producing cochineal used as a red dye for clothing. Other characteristic plants of the

Ottoman Empire: Historical Archaeology, Fig. 2 Eighteenth century Ottoman merchant's house at Ramla in Palestine/Israel. (Photo: Author)

Ottoman period include tulips and cypress trees, both of which had considerable social and economic significance. For example, the cultivation and sale of tulips was of such importance in the early eighteenth century that the era was known as the Tulip Period (*Lale Devri*), while cypress trees were regarded as symbols of life and were often planted in cemeteries.

International Perspectives

Although there are certain issues and areas of interest to archaeologists which can be traced throughout the empire and over different time periods, there are some distinctively regional patterns and historical perspectives which can be discussed as discrete units. For ease of discussion, the empire can be divided into four large regions which are the (1) Balkans, (2) Anatolia and the Black Sea littoral, (3) the Arab Middle East, and finally (4) Egypt, Cyprus, and North Africa.

In addition to the regions within the empire, it is perhaps worth considering the possibility of investigating Ottoman archaeology beyond the borders. Examples might include the activities of slave traders in Africa (e.g., Lane and Johnson 2009), the presence of the Ottoman navy based in Toulon in France in the sixteenth century, or the Ottoman influence on fortifications and warfare in Southeast Asia.

The Balkans

The Balkan Peninsula is an extremely mountainous area of southeastern Europe which is bounded to the west by the Adriatic Sea to the south by the Ionian and Aegean Seas and to the east by the Black Sea. The northern boundary of the peninsula is marked by the Danube as well as the Sava and Kupa rivers. Linguistically, the area is highly heterogeneous with a number of diverse language types spoken including Slavic, Romance, Hellenic, Albanian, and Turkic. Historically, the Balkans are one of the oldest parts of the Ottoman Empire with Thrace conquered in the mid-fourteenth century. By the end of the same century, both Serbia and Bulgaria were also under Ottoman domination. In 1463, Bosnia and Herzegovina were annexed, and during the 1500s Hungary and Romania were added to the Ottoman possessions. An indication of the strength of Ottoman control in the region can be seen from the fact that they were able to besiege Vienna as early as 1529. The antiquity of the Turkish presence in the region is reflected in the use of a Turkish name for the peninsula (Turkish *Balkan* = forested mountain chain).

The archaeology of the Ottoman Balkans (e.g., Figs. 3 and 4) is politically one of the most contentious areas of enquiry with territorial, religious, and ethnic divisions continuing to influence how archaeology is practiced and publicized (e.g., Meskell 1998). Within each of the modern states of the Balkans, there is a different attitude to the Ottoman past and of course its archaeology. This has meant that archaeological projects and publications focusing on the Ottoman era are more common in some of the countries of the region. For example, Hungary which was occupied by the Ottomans for a relatively short period (1541–1699) has a thriving tradition of Ottoman archaeology (e.g., Gerelyes and Kovács 2003). The extent to which the Ottoman past is incorporated into the national heritage can be seen by the Gül Baba monument in Budapest. Gül Baba was a companion of Süleyman the Magnificent who died during the Ottoman siege of Budapest in 1541. The tomb, which was built between 1543 and 1548, remained a prominent landmark after the Hapsburg reconquest of the city in 1686. In the nineteenth century, the shrine was restored by the Ottoman government, and the site is now registered as a Hungarian National Monument. The site which is now owned and maintained by the Turkish government is often referred to as the most northern Muslim pilgrimage site.

Other Balkan nations have been less eager to investigate and incorporate their Ottoman past into their national heritage. For a long time, the archaeology of the Ottoman period in Greece was regarded with suspicion (e.g., Bintliff 2007: 221). This was not necessarily a reflection of the country's attitude to its Ottoman past but rather an expression of difficult relations with the Turkish Republic. However, recently this approach has begun to change spurred on partly by the work of

Ottoman Empire: Historical Archaeology, Fig. 3 Sixteenth century Ottoman bridge in Mostar, Bosnia-Herzegovina. Destroyed 1993 rebuilt 2004. (Photo: Anthony Grey 22.9.11)

foreign archaeologists in Greece and partly by generally improving relations with the Turkish Republic. Important studies include the interdisciplinary Boeotia project which combines archival source material with field survey to define a pattern of settlement during the period of Ottoman rule (Kiel 1997). There have also been recent studies of Ottoman architecture in Greece, most significantly the volume produced by the Greek Ministry of Culture (Brouskari et al. 2009). In Bulgaria there has also been limited interest in the archaeology of the Ottoman period although there have been extensive historical publications dealing with this period. Guinova's 2005 publication provides a useful synthesis of recent work on Ottoman archaeology in the country.

Anatolia and the Black Sea

The modern Turkish state is more or less identical with the geographical region of Anatolia (sometimes also referred to as Asia Minor) and represents the heartland of the Ottoman state. Anatolia is bounded to the south by the Mediterranean, to the west by the Aegean, and to the north by the Black Sea. The Ottoman capital of Constantinople stands at the northwest corner of Anatolia straddling the narrow opening connecting the Black Sea to the Mediterranean. Historically, the Black Sea region was a border zone between the expanding Russian and Ottoman Empires and for convenience can be placed in the same region as Anatolia.

Despite the fact that the Turkish Republic is the direct successor of the Ottoman Empire, the attitude of modern Turkey to its Ottoman past has been ambiguous. Kemal Attaturk, the founder of the modern state, rejected the Ottoman past as "stale and unprofitable" (Finkel 2005: 1). The break with the past was symbolized by the change from the old imperial capital of Constantinople to Ankara located on the central Anatolian plateau. The emphasis within history and archaeology was on Anatolian civilizations and the Central Asian roots of the Turkish people (Özdoğan 1998). Although some Ottoman architecture was praised, the whole period was characterized as one of decline and of little relevance to the modern state. Until recently the majority of excavations and surveys in Turkey have focused on the prehistoric and pre-Islamic periods, and where the Islamic sites were investigated, the emphasis was on the medieval Seljuk remains rather than on the later Ottoman remains. Indeed, one commentator writing at the end of the 1990s wrote "with justification we can claim that during the last decades more Ottoman archaeology has been destroyed than any of the earlier periods since public opinion still posits that Byzantine and Greco Roman remains are antique whilst Ottoman ones are not" (Özdoğan 1998). However, since the late 1990s, there has been an increasing interest in Ottoman archaeology in Turkey partially reflecting a worldwide tendency of interest in the more recent past and also reflecting political changes in Turkey which have begun to see the Ottoman Empire in a more favorable light.

Apart from the coasts of Anatolia and Bulgaria, the Ottoman area of control on the Black Sea falls mostly within the Republic of the Ukraine. The region was first incorporated into the Ottoman realm in 1538 during the reign of Süleyman the Magnificent (r. 1520–1566) though the control of anything beyond the shores of the Black Sea was largely a matter of alliances rather than direct control. The Ottoman presence in these areas was mostly in the form of fortresses which remained in Ottoman control until the early nineteenth century. For examples of Ottoman archaeology in the Black Sea region, see Kellner-Heinkele et al. (2008). A summary of archaeological work on Ottoman monuments in Ukraine can be found in Bilyayeva and Ersoy (2008).

The Arab Middle East

The Arab Middle East is a term of convenience used to describe the Arab provinces incorporated into the Ottoman Empire during the early sixteenth centuries. This area comprises the modern states of Syria, Iraq, Lebanon, Jordan, Palestine/Israel, and parts of Saudi Arabia and Yemen. This area remained part of the Ottoman Empire for nearly 400 years and had a special distinction in that it contained both the spiritual home of Islam as well as the capital cities of Damascus and Baghdad. Ottoman rule in this region was described in negative terms by European nineteenth-century travelers in the Middle East, and these accounts have informed many Western perceptions of a declining Ottoman Empire. This view was reinforced during the early twentieth century when the Ottomans supported the Germans in the First World War while the British supported an Arab revolt against Turkish rule. Set against this background, it is surprising that in this area the successor states have a more positive view of the Ottoman period, and it is in this area that Ottoman archaeology is most developed. Studies of Ottoman monuments began as early as the 1930s when Jean Sauvaget (1937) published his survey of Ottoman caravanserais in Syria. In general, however, studies of the Ottoman period only became common from the 1980s

as techniques improved and recent centuries were considered legitimate subjects of archaeological investigation. A summary of historical and archaeological work in the area can be found in McQuitty (2001). The archaeology of the Ottoman period in Iraq has been less studied partly because the Ottoman presence in the area was more disrupted (this formed a border zone between the Saffavid and Ottoman Empires) and partly because of disruptions due to almost continuous warfare since the 1980s. However, Simpson's (2011) article based on fieldwork in the North Jazira provides an interesting summary of Ottoman archaeology in northern Iraq.

Within the Arabian Peninsula, Yemen and Saudi Arabia contain significant numbers of Ottoman sites and monuments, yet in both cases, for different reasons, there has been little investigation of the archaeology of the Ottoman period. In Yemen, civil war and social unrest have meant that investigations of the Ottoman period have been limited, whereas in Saudi Arabia there has been an ideological reluctance to recognize the Ottoman presence, as indicated by the destruction of Ottoman monuments in Mecca and Medina.

Yemen was incorporated into the Ottoman Empire in the sixteenth century though by the 1630s Yemeni forces succeeded in ousting the Turks. The Ottomans returned in 1872 and retained control of the Yemeni highlands until they were expelled in 1914. There have been few specific studies of Ottoman period archaeology though Ottoman period sites are mentioned in a large number of archaeological surveys. Ottoman architecture in Yemen has also been investigated as part of its wider historic heritage as well as a distinct architectural period (Farah 2011).

Two areas within Saudi Arabia were incorporated into the Ottoman regime, the Al-Hasa Oasis on the eastern coast and the Hijaz on the Red Sea coast. In addition to Ottoman buildings in Mecca and Medina, the Hijaz contains Ottoman forts along the Hajj routes (Fig. 5) as well as nineteenth-century forts associated with the Ottoman reconquest. The Al-Hasa area contains a number of Ottoman buildings including the mosque of Ibrahim.

Egypt, Cyprus, and North Africa

Egypt was incorporated into the Ottoman Empire in 1517 following the defeat of the former Mamluk rulers. In terms of population Egypt was the largest Arab province within the Ottoman Empire and as such had certain degree of autonomy which increased in the 1800s to virtual independence. In terms of archaeological research, there has been

Ottoman Empire: Historical Archaeology, Fig. 5 Ottoman Hajj fort at Mudawwara on the border of Jordan and Saudi Arabia. (Photo: Author)

an emphasis on the pre-Ottoman medieval periods both because they are more distant in time and because they are considered to be more "Egyptian" (i.e., not under foreign domination). Ottoman architecture, on the other hand, has received considerable academic attention particularly in Cairo where new architectural forms were introduced. Outside Cairo there have been a few archaeological projects which have focused on Ottoman period remains: examples include the Japanese project at Al-Tur in the Sinai (Kawatoko 1995), the excavation of Ottoman Quseir (LeQuesne 2007), and the excavation of Qasr Ibrim.

Further south in the territory of modern Sudan, the Ottomans established a presence along the Nile valley as early as the sixteenth century though the whole country was only incorporated into the Egyptian Ottoman Empire in the nineteenth century (a useful summary of Ottoman archaeology in Sudan can be found in El-Zein 2009).

The Ottoman presence in North Africa to the west of Egypt has a different character to the Balkans, Anatolia, and the Arab Middle East, though there may be some similarities to the north coast of the Black Sea. The Ottoman presence was generally limited to the coastal cities with very little influence on the interior. In many ways North Africa served as a series of naval bases which served both official Ottoman naval operations as well as local corsairs who raided throughout the Mediterranean and beyond. Little research has been carried out into the Ottoman archaeology of this area (cf. Heywood 2009), although a few studies show the potential for further work.

In regional terms it is difficult to position Cyprus within the Ottoman Empire. It has strong links to the Balkans through the Greek-speaking population and links to Anatolia and Syria through proximity and trade but are included in this section as representative of the Ottoman presence in the Mediterranean. The continuing cultural complexities of Greek and Turkish Cyprus have had obvious implications for the investigation of the Ottoman archaeology of the island; however, there have been some interesting studies which reflect this complexity (e.g., Given 2000).

Future Directions

It can be seen that archaeology of the Ottoman period already encompasses a vast area and many different forms of human settlement and interaction. Much remains to be done in integrating textual research with archaeology and also with environmental studies. Several areas with potential for further exploration include the archaeology of slavery within the Ottoman Empire (e.g., Lane and Johnson 2009); the visibility and interactions between various ethnic, religious, and social groups; long distance trade in particular connections with the Indian Ocean and the Atlantic; and the role of archaeology in developing an international heritage.

Ounjougou Site Complex, Archaeology of the

Eric Huysecom
Laboratoire Archéologie et Peuplement de l'Afrique, Université de Genève, Geneva, Switzerland

Introduction

The Malian site complex of Ounjougou is located in the Boucle du Niger (or Niger Bend) in the Dogon Country, more precisely on the Bandiagara Plateau about 15 km east of the town of the same name (Fig. 1). It includes more than a hundred archaeological sites in a valley around the confluence of four rivers, of which the main one, the Yamé, joins the Niger 30 km north of the town of Mopti. Topographically, this zone presents as a series of gullies cut through a complex succession of Quaternary eolian, alluvial, and colluvial formations (Lespez et al. 2011). The stratigraphic sequence, which can in places be 16.50 m thick, has yielded archaeological material from the Lower Paleolithic to the present. The deposits also contain abundant vegetal remains (pollen, leaves, charcoal, wood, seeds, etc.) of excellent preservation. As a result, the site complex offers

Ounjougou Site Complex, Archaeology of the, Fig. 1 Location and geomorphological presentation of the site of Ounjougou. *1*: Sandstones and scarps in sandstones; *2*: Main terrace-glacis; *3*: Eroded sectors of main glacis; *4*: Holocene terrace (8th millennium BCE); *5*: Secondary terrace-glacis; *6*: Sands and silts of alluvial accumulation; *7*: Hydrographic network and permanent lakes; *8*: Stratigraphic limits; *9*: Terraces and glacis edges; *10*: Track and relics of the colonial track; *11*: Height (meters); *12*: Archaeological sites; *13:* Infiltration of Boumbangou through sandstones; *14*: Paleoriver of Yamé. the possibility to place human occupations in relation to climatic and environmental changes over a long chronological sequence.

After the discovery in 1994, 13 field seasons were undertaken between 1997 and 2009 in the framework of an international and interdisciplinary

research program entitled *Human settlement and paleoenvironment in West Africa*, with 12 research institutes involved from Mali, France, Germany, and Switzerland and coordinated by the Swiss Archaeological and Ethnoarchaeological Mission in West Africa (MAESAO), now the *Laboratoire Archéologie et Peuplement de l'Afrique* at the University of Geneva (Huysecom 2002). Research carried out in this program has contributed many elements that have significantly changed our understanding of the prehistory and history of the Dogon Country, and more broadly of West Africa. In addition, while remaining attentive to the causes that lead to migration or technological innovation, they have confirmed that climatic variations that affected the modern Sahel region throughout the Pleistocene and Holocene had a decisive effect on human groups and their adaptive responses, whether by controlling the environment by systematic burning or by developing ceramics, herding, and agriculture.

Key Issues/Current Debates/Future Directions/Examples

Paleolithic Occupations

The earliest evidence of human occupation is seen at several sites in the complex where the lithic industry contains polyhedrons and sub-spheroids in quartzitic sandstone associated with worked cobbles (Soriano et al. 2010) (Fig. 2). These artifacts, which reflect an early phase of the Paleolithic by their typological and technological traits, were observed in stratigraphic context, sealed in plates of coarse sands adhering to bedrock. An OSL date for the Final Middle Pleistocene was obtained for the deposits overlying these formations, providing a terminus ante quem of 180 ka for this lithic industry. The degree of arenization (surface weathering) of the plated layers in which this industry was discovered, suggests that these deposits underwent long periods of leaching under damp warm conditions, and on typo-technological comparisons with Paleolithic material from the Maghreb, an age between 1 and 500 ky can be considered for this polyhedral industry at Ounjougou (Soriano et al. 2010).

Although having a broad archaeological visibility, the Acheulean is still absent across the entire Ounjougou zone, the Bandiagara Plateau, and the Seno Plain. This may indicate the existence in West Africa of regions not frequented by Acheulean populations, although they are well represented in neighboring regions.

A Levallois core with preferential removals, found isolated in stratigraphic context, marks the first evidence for the Middle Paleolithic at

Ounjougou Site Complex, Archaeology of the, Fig. 2 Polyhedron extracted from the deepest sedimentary formations of Ounjougou

Ounjougou Site Complex, Archaeology of the, Fig. 3 The Levallois industry of the site of Ounjougou – *Orosobo 2*, dated to 35–30 ky: Lithic industry on quartz. 1–6, Levallois cores; 7–10, Levallois flakes

Ounjougou (Fig. 3). An OSL date places this core around 150 ky, in the Late Middle Pleistocene. Middle Paleolithic occupations in the Ounjougou site complex, all open air, become more common during the Upper Pleistocene: 25 typo-technologically distinct assemblages were identified between 100 and 22 ky, with a particular concentration during oxygen isotope stage 3 between 50 and 30 ky (Rasse et al. 2004; Soriano et al. 2010). All of the known occupations are open-air sites, and the lithic material for most of them is preserved in primary position or very slightly reworked in colluvial silts. Most of the reduction techniques typically recognized are represented at Ounjougou: Levallois, discoidal, unidirectional, blade, and facies with leaf-shaped bifacial pieces. The lack of technological recurrence in the chronological succession of lithic industries at Ounjougou raises questions, particularly given their diversity. We nearly never find two successive occupations with the same lithic industry. The diversity of lithic industries found in stratigraphic context at Ounjougou and their sequence without obvious logic further raises questions about population dynamics in Sahelian West Africa during the Upper Pleistocene. Even more than the observed diversity is the rate of change, which is very high since the most of the known occupations are situated during OIS 3 over a period of 30 ky years. The succession seen at Ounjougou enables us to reject the hypothesis of gradual local evolution in technological traditions for this period. It suggests rather that human groups with different technological traditions regularly succeeded one another in the region (Soriano et al. 2010).

During OIS 2, after 22 ky, the Ounjougou region underwent extremely arid conditions and appears to have been deserted by humans until the climate improved at the onset of the Holocene (Rasse et al. 2004).

Holocene Occupations

The discovery of ceramic sherds associated with grinding tools and small bifacial armatures in Holocene layers dated to the beginning of the

Ounjougou Site Complex, Archaeology of the, Fig. 4 Ceramic sherds from stratigraphic unit HA1 of Ounjougou – *Ravin de la Mouche*, older than 9400 cal BCE, including a bowl fragment (**a**) and a decorated sherd (**b**)

10th millennium cal BCE and to the 8th mill. Cal BCE has significantly altered the state of archaeological knowledge (Huysecom et al. 2004, 2009; Soriano and Huysecom 2012) (Fig. 4). Indeed, these are the oldest ceramic known today in sub-Saharan Africa. The solid stratigraphic and chronological context of the site of *Ravin de la Mouche* at Ounjougou (Rasse et al. 2006; Lespez et al. 2008; Neumann et al. 2009; Ozainne et al. 2009) indicates that knowledge of ceramic production appeared in sub-Saharan West Africa at least as early as in the Nile Valley, prior to 9400 cal BCE. This innovation, as well as very specific bifacial armatures, is probably linked to the reoccupation of the open tropical savannas that regenerated in the Dogon Country at the start of the Early Holocene. This new typo-technological complex would have spread rapidly to the north, particularly toward the central Sahara, at the same time as the movement of the front of intertropical convergence, when the Saharan zone became increasingly green, developing surfaces of edible grasses and major changes in the composition of wild fauna hunted.

During the Middle and Late Holocene, around the 5th and the mid-3rd mill. Cal BCE, we observe two phases of human reoccupation, at the sites of *Promontoire Néolithique* and *Ravin du Hibou*, showing affinities in their material culture with some Neolithic complexes in the central Sahara (Huysecom et al. 2004; Kouti and Huysecom 2007). A millennium later, during the seventeenth and sixteenth centuries cal BC, cultural complexes of the Final Neolithic that developed in the Ounjougou region present unique traits, with the appearance of pottery decorated by different kinds of roulettes with highly characteristic motifs (Ozainne in press). The existence of stone dwellings along the river, with grinding materials and abundant calcined grass stalks, is established, while the practice of millet (*Pennisetum glaucum*) agricultures is confirmed by the discovery of burned seeds dated by AMS. The Neolithic occupations were abandoned near the middle of the 1st mill. Cal BCE (Ozainne et al. 2009; Ozainne in press).

Protohistory

Protohistoric occupations over the last two millennia are less well represented at the site complex, maybe following a dry episode during the first centuries BCE/CE (Mayor et al. 2005). Excavations at *Promontoire protohistorique*, with a sequence of colluvial layers, document the domestic pottery used between the seventh and thirteenth centuries CE by populations who settled in the region prior to the arrival of the Dogons. The excavation of a rockshelter with ritual function, *Dangandouloun*, yielded abundant ceramic material of excellent quality, including jars, bowls, and many tripod cups, as well as iron weapons and ornaments (Fig. 5). A series of thermoluminescence dates places this set of objects between the seventh and twelfth century CE. Stylistic and technical analyses of the ceramics have demonstrated the primarily local production of pottery by a group of the Gur linguistic family, shaped by pulling out of a lump of clay, the use of recipients produced by Mandé groups from the Inland Niger Delta and rare importing of recipients produced on the Seno Plain or further east, shaped by pounding in a concave form above a straight mat. This indicates that the Bandiagara Plateau was located at the crossroads of at least three

Ounjougou Site Complex, Archaeology of the, Fig. 5 Pottery from the ritual rockshelter of Dangandouloun, dated between the seventh and the twelfth century CE, notably including numerous tripod cups

large cultural spheres from the second half of the 1st mill. CE (Mayor 2011).

In addition, the study of modern and past ceramic traditions, through the excavation of historical sites and collection at abandoned villages known by oral tradition, has enabled us to follow changes in styles through time and to formulate hypotheses concerning the settlement of the plateau. Finally, the reconstruction of very complex Dogon migration routes on the plateau over the last three to four centuries, understanding of the relationships that were established between the different clans, and the delimitation of ancient territories, at the heart of current land ownership disputes, were made possible through oral tradition survey (Mayor et al. 2005).

Ethnoarchaeological research has moreover been extensively undertaken for the modern ceramic traditions of the region and has enabled identification of a peasant tradition (tradition A) in the center of the Dogon Country and a series of traditions made by the wives of smiths (traditions B, C, and D). The latter are either of local origin or from societies on the periphery of this region. The map of these traditions is extremely useful to interpret archaeological remains, particularly those from the Ounjougou site complex (Mayor 2011). Finally, archaeological and ethnohistorical studies have been carried out with the smith clans and traditional iron production on the Dogon Plateau during the period between the last precolonial empires (mid-2nd millennium CE) and the arrival of French colonization (late nineteenth to early twentieth century). They have made it possible to develop an overall scenario for the history of settlement of smiths in the region and their production and to situate them within the dynamics of the central Nigerian plateau (Robion-Brunner 2010).

O

Introduction

Around 100,000 years ago, the world was inhabited by a heterogeneous group of hominins: the Neanderthals in Europe and Western Asia, Denisovans and possibly other primitive hominins in East Asia, *Homo floresiensis* on the Indonesian island of Flores, and more modern-looking humans in Africa and the Middle East. By around 30,000 years ago, most of this diversity had disappeared, and modern humans occupied much of the Eurasian continent. How did this transition occur?

Definition

The Out-of-Africa Origins model (also Recent African Origin) was developed by several workers during the 1980s and was discussed in some detail by Chris Stringer and Peter Andrews (Stringer and Andrews 1988). The hypothesis is that the modern form of *Homo sapiens*, or anatomically modern humans (and probably also fundamental aspects of modern human behavior), had evolved in Africa by at least 150,000 years ago. Around 60,000 years ago, modern humans left Africa, replacing archaic hominins outside of the continent with restricted amounts of interbreeding.

Key Issues/Current Debates/Future Directions/Examples

The origins and spread of modern humans have been hotly debated throughout the history of paleoanthropology. There are several hypotheses that explain modern human origins. The first is the Out-of-Africa or Recent African Origins hypothesis (Fig. 1). This hypothesis states that modern humans and modern human behavior evolved in Africa and then spread from Africa around 60,000 years ago, replacing archaic hominins with restricted amounts of interbreeding (Fig. 1). The second hypothesis is the regional continuity or multiregional model and proposes that modern humans evolved in parallel across the globe from the hominins that lived there at the time, with gene flow between the different lineages. A third hypothesis is the assimilation model. This model proposes a middle ground and states that modern humans evolved in Africa, but they merged with the local hominins, resulting in hybrid populations. With advances in scientific methods and additions to the fossil record, these hypotheses are ever changing, but their essence remains the same.

Below are the arguments supporting the Recent African Origins model. Evidence from the fossil record indicates that the African continent gave rise to modern humans. Both morphological and behavioral modernity evolved in Africa between ca. 300,000 and 100,000 years ago. These people would then have spread throughout Africa and across the rest of the world, replacing the other hominins with little gene flow between them. Genetic evidence from mitochondrial and Y-chromosome DNA supports this hypothesis, while nuclear DNA shows that there were also several episodes of interbreeding between *H. sapiens* and other human species (Kuhlwilm et al. 2016.

Out-of-Africa Origins, Fig. 1 Three models of modern human origins. *Left*, Out-of-Africa model; *middle*, multiregional model; *right*, assimilation model

Fossil Evidence

Until recently it was believed that the oldest modern human fossils came from East Africa and date to about 160–195,000 years. Fossils from Omo and Herto show some primitive features, but, at the same time, some derived *Homo sapiens* characteristics such as a rounded skull with high forehead, a chin, and a short face that is tucked under the large brain case. In 2017, the Moroccan site of Jebel Irhoud was dated by thermoluminescence and ESR to about 315 ± 34 thousand years old. The cranial material shows some derived *Homo sapiens* traits, such as in its facial, mandibular, and dental morphology, but retains a more primitive neurocranial and endocranial morphology. This material may be evidence of early *Homo sapiens* evolving first in North Africa, rather than East Africa (Hublin et al. 2017).

There is fossil evidence from other parts of Africa that modern humans also lived there at least 100,000 years ago. At Klasies River Mouth in South Africa, for example, the remains of several individuals have been found that suggest some modern affinity. Although the fossils are fragmentary, archaeological evidence from the same site has been described as presenting aspects of behavioral modernity. More complete modern human fossils from Qafzeh and Skhul Caves in Israel are dated to around 110,000 years. Environmental evidence has shown that modern humans were present in this region during a warm and wet period, possibly between phases of Neanderthal's occupation. Other Afro-Arabian mammal species are also present in the archaeological deposits from that time and suggest that this was a small-scale migration into the Levant due to favorable climatic conditions that suited the African fauna.

The earliest fossil evidence for morphologically modern humans outside of Africa comes from sites such as Lake Mungo in Australia (<42,000 BP), Niah Cave in Sarawak (<40,000 BP), Tianyuan Cave in China (<40,000 BP), Tam Pa Ling Cave in Laos (~55,000 BP) (Demeter et al. 2015), Ust'-Ishim in Siberia (~45,000 BP) (Fu et al. 2014), and European sites such as Cavallo Cave and Kents Cavern (40–43,000 BP (Benazzi et al. 2011; Higham et al. 2011). Accompanying some of these fossils is evidence of modern human tools and artifacts. The exodus out of Africa is believed to have been firstly via a coastal route into eastern Asia and down into Australasia. Australasia appears to have been a stepping stone for the peopling of some of the other Pacific Islands by 5000 years ago. Northeast Asia served as the gateway to North and South America by 20,000–15,000 years ago. To date, no morphologically modern humans have been well dated outside of Africa to more than 55,000 years ago, apart from those at Skhul and Qafzeh in the Near East, although there are claims for modern human teeth from Fuyan Cave in China dating to at least 80,000 BP.

Genetic Evidence

Until recently, it was impossible to extract intrinsic DNA from fossils. Therefore, until the end of the twentieth century, genetic research in the field of paleoanthropology was limited to the study of modern human and living primate DNA. Modern human diversity in different types of DNA (mitochondrial, Y-chromosome, and nuclear [autosomal] DNA) enables us to look at the demography of humans' ancient ancestors, the size of the ancestral population, and the number of humans that may have left Africa to populate the rest of the world. DNA can also be used to estimate dates for some key events.

Mitochondrial DNA (mtDNA) is found in the mitochondria, which are small organelles that are involved in energy processing inside the cell. mtDNA is inherited by both males and females from their mother's ovum. Mitochondrial DNA does not undergo recombination but can carry a novel mutation in the child. Many of these mutational changes are introduced at a slow but steady rate. Despite its clear signal of ancestry and descent, mtDNA studies have received criticism because they cover a limited amount of genomic coding compared to the whole DNA sequence. At the same time, the small size of the genome and its limited coding means that it is easier to sample and sequence, and mutations can be easily tracked. Results of mtDNA analysis show that

Out-of-Africa Origins, Fig. 2 Map showing the spread of model human groups as traced using mitochondrial DNA (numbers refer to 1000 years ago). Routes shown are notional, not precise. (From The Origin of our Species etc. Credit: Silvia Bello)

the African lineages contain the greatest diversity, indicating that they had the longest time to diverge and are therefore the oldest lineages. This is consistent with Africa being the place of origins of all modern humans. Because the amount of mutation is proportional to time passed, mtDNA can be used to estimate the date when the "mother of all living mtDNA" or "mitochondrial Eve" lived (Fig. 2) and how large the pool of ancestral females was. Although mtDNA mutation rates are not perfectly understood, and therefore dating is still approximate, results from mtDNA studies show that the ancestral population of humans must have been in Africa and perhaps consisted of around 10,000 individuals, with the latest estimate for the mitochondrial origin dating to around 150,000 years (Endicott et al. 2010).

Y-chromosomal DNA is inherited by males from their fathers and carries very few genes. It can only be used to infer the evolutionary history of males. It has received less attention than mtDNA, but in recent years, the Y-chromosomal DNA for a large worldwide sample has been fully sequenced and has yielded some important data on human history. The theoretical "Adam" had been estimated to have lived approximately 70,000 years ago, though recent research has more than doubled that age estimate, and the deepest branches again appear in Africa, supporting an African origin for all modern humans.

The study of autosomal or nuclear DNA has also been used to reconstruct human population history, and analyses of different sequences have largely supported the results from mitochondrial and Y-chromosomal DNA in confirming the same pattern: the greatest amount of variation is present in Africa, and DNA diversity steadily declines with overland distances from Africa. This decline in diversity is also picked up in the morphometry

of skulls in populations from different parts of the world.

In 1997 the first ancient mtDNA was extracted from Neanderthal bone. Since then, some 30 Neanderthal fossils (Green et al. 2008) have been sequenced, showing that mtDNA diversity in Neanderthals was much lower than that of modern humans. In addition, the results strongly indicate that Neanderthals made no lasting contribution to the human mtDNA gene pool. This does not mean, however, that they did not contribute to the nuclear DNA of humans.

In 2010, a nearly complete Neanderthal nuclear genome was published for the first time (Green et al. 2010). That same year, the nuclear DNA of the Denisovans, a previously unknown population that has distinct DNA from modern humans and Neanderthals, was published. This population is known only from a few fossil specimens, but DNA analysis has indicated that this population may have been relatively widespread in Southeast Asia before modern humans migrated into the area, somewhat like Neanderthals were widespread throughout Europe and Western Asia when modern humans arrived there (Slon et al. 2017; Reich et al. 2010).

Contrary to the results of the mtDNA, nuclear genome analysis indicates that humans interbred with both Neanderthals and Denisovans. About 2% of Neanderthal DNA is still present in non-African DNA today, and Denisovan DNA is additionally present in the genome of modern-day Australasians at a level of around 4%. These levels of interbreeding are low but significant, and ongoing analysis is focused on the ways in which these genetic differences between Neanderthals, Denisovans, and modern humans would have manifested phenotypically and how shared DNA might have been advantageous to modern humans (e.g., protection from endemic diseases).

The genomic evidence confirms that humans have a predominantly recent African Origin. Yet, at the same time, it is evident that considered globally, *Homo sapiens* is not entirely Out-of-Africa and that a limited amount of interbreeding with populations outside of Africa had occurred.

Overseas Chinese Archaeology

Douglas E. Ross
Albion Environmental, Inc., Santa Cruz, CA, USA

Introduction

Since its beginnings in the Western USA in the late 1960s, Overseas Chinese archaeology (or Chinese diaspora archaeology) has developed from an uncoordinated collection of primarily descriptive site reports to a rapidly unifying, interdisciplinary, and international field employing sophisticated theoretical approaches in an increasingly contextual and comparative manner. Its significance lies in its potential for addressing themes related to migration, race, and ethnicity, cultural persistence and change, and other topics of wider archaeological relevance.

Definition

Chinese diaspora archaeology focuses on material remains associated with individuals and communities of Chinese descent living abroad, typically in the context of nineteenth- and early-twentieth-century global population movements. It includes both first-generation Chinese immigrants and their naturalized descendants. Studies have been undertaken from a range of theoretical perspectives, and there are currently no dominant research paradigms. To date, research is largely restricted to the USA, Canada, Australia, and New Zealand but could include any country to which Chinese migrated over the past several 100 years or more. Generally excluded are sites not occupied by ethnic Chinese (broadly conceived) but where Chinese-manufactured objects, including coins and export porcelain, have been found. However, the field may encompass the influence of Chinese

migrants and material culture on their non-Chinese neighbors and others with whom they interacted.

Field projects have explored a range of urban and rural contexts, site types, and features. They include industries such as logging, mining, dam and road construction, railroad construction and maintenance, charcoal burning, fish canning, shrimp and abalone harvesting and processing, and market gardening, as well as stores, restaurants, laundries, boarding houses, gambling halls, temples, cemeteries, and cooking features, among others (Fig. 1). Sites are typically identified through historical records or the presence of one or more classes of imported Chinese consumer goods, including ceramic table and storage wares, opium paraphernalia, glass pharmaceutical and beverage bottles, coins, and gaming artifacts. Chinese merchants developed large-scale distribution networks for imported foods and other goods that reached even the most remote labor camps (Fig. 2). Consequently, Chinese sites have been comparatively easy to identify archaeologically, although direct equation of objects with ethnicity remains interpretively problematic and risks overlooking Chinese-occupied sites that lack imported artifacts.

While many studies have been explicitly archaeological, others have drawn together a range of archival, oral history, and archaeological data to develop historical syntheses of individual regions or local communities. Detailed artifact studies have been conducted on Chinese ceramics, opium paraphernalia, coins, and faunal remains, and important work has also been done on standing architecture and in situ collections of objects recovered from such structures.

Historical Background

Overseas Chinese archaeology emerged in the USA in the context of heightened interest in civil rights, social history, multiculturalism, and ethnicity in the 1960s, along with the advent of legally mandated resource management archaeology. Early studies were conducted in the late 1960s and 1970s in the Western USA, including pioneering work on Chinatowns in California, Nevada, and Arizona. Other projects were

Overseas Chinese Archaeology, Fig. 1 Reconstructed Chinese laundry, Barkerville, British Columbia

Overseas Chinese Archaeology, Fig. 2 Cabinets of imported merchandise in a reconstructed Chinese store, Burnaby Village Museum, British Columbia

completed on railroad construction camps in California and Texas, a rural Chinese store and an industrial borax works in California, and a salmon cannery in Oregon. Most work was done in a resource management context, in which Chinese sites were not a self-conscious research objective.

In the 1980s and 1990s, Overseas Chinese archaeology developed into a distinct field of study in the Western USA marked by an increase in the volume and diversity of research, including sophisticated resource management studies and an increasing number of graduate theses (Voss and Williams 2008). Onset of this coalescence is marked by the founding of the Asian American Comparative Collection (AACC) at the University of Idaho in 1982 and publication of two comparative studies of ethnicity incorporating research from Chinese sites (McGuire 1982; Schuyler 1980). The first was an edited volume combining chapters on African and Asian American archaeology, while the second used archaeological data to develop a model of ethnic group formation and change rooted in boundary maintenance. The AACC is a research resource for archaeologists housing an extensive comparative collection of Asian artifacts commonly found on overseas sites plus a sizeable reference library (Fig. 3). It is overseen by volunteer curator Priscilla Wegars, who also edits the AACC's quarterly newsletter.

Throughout this period, most projects continued to be driven by resource management imperatives that included large-scale urban redevelopment projects, although some academic institutions like the Universities of Idaho and Nevada undertook research-oriented excavations. Most studies also focused on descriptive summaries of archaeological findings, including functional artifact typologies. Major resource management projects were undertaken on historic Chinatowns in California, including San Francisco, Sacramento, Oakland, Los Angeles, Riverside, and San Jose, along with Chinatowns in several other states. Work was also done on a range of rural labor camps and related industrial sites across the West but typically on a much smaller scale. Since the 1990s, resource management and academic studies have grown exponentially in quantity and quality, including an expanding volume of published works and a large number of graduate theses.

Early research results were largely contained in unpublished reports and theses, although the 1980s and 1990s saw publication of major monographs on Chinatowns in Los Angeles, Riverside, and Woodland, California (Felton et al. 1984;

Overseas Chinese Archaeology, Fig. 3 Chinese artifacts in the Asian American Comparative Collection, University of Idaho

Great Basin Foundation 1987; Greenwood 1996), along with an edited volume on Overseas Chinese archaeology (Wegars 1993). Wegars' volume addresses rural and urban contexts, work and leisure, analytical techniques, and comparative and theoretical studies. It ranges from local case studies focusing on archival records, rural dwellings and terraced gardens, ethnic boundary maintenance, and the presence of Chinese women to comparative analyses of faunal assemblages and pioneering studies of opium paraphernalia and Asian porcelains. It concludes with a survey and critique of the field by Greenwood. These volumes synthesize large quantities of historical and archaeological data, including numerous individual studies of Chinese traditions and material culture. However, chapters are often compartmentalized rather than building toward an integrated picture of Chinese immigrant life.

Although addressing a range of interpretive themes, much early literature adopted an acculturation paradigm and subscribed to linear, mechanical models of cultural persistence and change that assumed a direct correlation between artifacts and culture. Based on the frequency of imported Chinese artifacts, many studies concluded that Chinese maintained their traditional culture, resisted acculturation, and insulated themselves in ethnic enclaves. Such resistance was interpreted as agency and ethnic boundary maintenance on the part of Chinese immigrants. This approach has been subject to internal critiques beginning in the 1980s (Praetzellis et al. 1987; Voss 2005; Wegars 1993). These critiques have also challenged views of Chinese immigrants as internally homogeneous, when they varied widely in terms of language, class, ethnicity, economic status, and cultural traditions. Subsequently, there has been a gradual interpretive shift toward cultural exchange, fluid and dynamic identities, and strategic adaptation and selective accommodation to local Euro-American culture in particular local contexts.

Mary and Adrian Praetzellis were among the first to argue in favor of a contextual approach (Praetzellis et al. 1987). Their innovative resource management studies of Chinese merchants in Sacramento highlight the active role of material culture in immigrant social strategies. They show how merchants adopted Euro-American material culture while also maintaining homeland practices and manipulated both in their relations with non-Chinese business associates and Chinese laborers. A key observation was that retention of Chinese consumer goods and adoption of Euro-American ones can reflect a variety of factors besides

acculturation, including differential access and power relations. One of their main contributions was to demonstrate that, rather than simply reflecting a static ethnicity, material goods could be actively used to create and transform identities in particular contexts and to serve particular agendas.

Key Issues and Current Debates

The 1990s and Early 2000s

For most of its early history, Overseas Chinese archaeology had little impact on the broader discipline, largely because much of the literature was confined to unpublished reports and theses and remained underrepresented in peer-reviewed journals. Since the 1990s, however, studies of the Chinese diaspora have increasingly addressed core themes in historical archaeology and served as a valuable counterpoint to more established scholarship on the African and European diasporas (Voss and Williams 2008). Such themes include migration, racialization, identity, cultural persistence and change, capitalist economics and labor relations, gender and sexuality, urbanization, and material consumption, among others. In the 2000s, scholars also began incorporating it into disciplinary syntheses and critical overviews of topics like racialization (Orser 2007) and material consumption (Mullins 2011). Asian American archaeology was also spotlighted in a 2004 thematic issue of the SAA Archaeological Record focused on ethnicity. A survey of graduate theses from this same time frame indicates a range of research foci, including acculturation and adaptation, intercultural encounters, material culture preferences, social landscapes and relations, skeletal biology, individual and community identity, globalization, technological change, racialization and discrimination, transnationalism and diaspora, material consumption, and the role of voluntary organizations.

A 2008 thematic volume of *Historical Archaeology* offers a sampling of some of the more sophisticated research that emerged in the USA in the early 2000s (Voss and Williams 2008). The paper by Voss and Allen provides an overview of Overseas Chinese history, historiography, and archaeology and offers critiques of the field and prospects for the future. The volume concludes with critical reflections on the field by Mullins and Yu from an archaeologist's and a historian's perspective. Other papers address immigrant responses to anti-Chinese movements; scales of analysis in Overseas Chinese communities; the lives of a solitary Chinese seaweed gatherer, California farm workers, and Chinatown residents in San Bernardino, California, and Deadwood, South Dakota; an urban Chinese American cemetery in Portland, Oregon; and a plantation cemetery in Hawaii. A particularly groundbreaking paper is Williams' gendered approach to interpreting material culture used by the predominantly male Overseas Chinese population rooted in multiple, competing discourses of masculinity. His work points to the need for a more explicitly gendered approach to the lives of Chinese migrants. In his contribution, Mullins cautions that ghosts of linear and universal models of acculturation still haunt the literature, along with a somewhat static and bounded (essentialist) view of Chinese culture, despite increasing recognition of ethnic identities as fluid and context dependent. He notes that the popular "accommodation" model of culture change differs markedly from the one adopted by archaeologists of African America, rooted in issues of power and inequalities across the color line. He argues that greater attention to the role of racism and race-based exclusion and inequality is needed in archaeological interpretations of Overseas Chinese. Furthermore, the overwhelming focus on migrants' agency and resistance to dominant ideology risks ignoring structural conditions constraining individual choice. Finally, Mullins cautions against overemphasizing the "strange and unusual" aspects of Chinese culture, including opium pipes, Asian ceramics, and gaming pieces, in ways that reify ethnic distinctions and stereotypes (Fig. 4).

In the same volume, Voss and Allen note that most archaeologists studying Overseas Chinese sites have little or no Chinese language training, and few take advantage of the full range of Chinese documents locally or in the homeland. Furthermore, comparative archaeological studies of

nineteenth- and twentieth-century sites in China are rare. They advocate for an overall approach that counters the lingering tendency to perceive Chinese communities as bounded and insular. Such an approach should focus on the interplay within and between ethnic and racialized populations and explore the role of cultural practices in the ongoing negotiation of fluid communities and identities in particular historical contexts, in the way that Praetzellis et al.'s (1987) and Lydon's (1999) pioneering research does.

Overseas Chinese Archaeology, Fig. 4 Chinese gaming pieces recovered from a salmon cannery near Vancouver, British Columbia

Studies increasingly demonstrated that, although they often lived in segregated communities and maintained aspects of homeland culture, Chinese migrants also combined inherited and adopted objects and practices and developed relationships with their non-Chinese neighbors while maintaining distinct ethnic identities. Adopted elements include drinking and dining habits, medicinal remedies, smoking, gaming, and clothing (Fig. 5). Sometimes this involved significant changes to traditional cultural practices but also reuse and recontextualization of non-Chinese objects and behaviors in unique ways. In fact, evidence of non-Chinese artifacts and behaviors has been documented archaeologically from the beginning. However, under the acculturation paradigm, it was largely ignored or rationalized as a product of mixed assemblages or as limited adaptation born of necessity (Voss 2005).

An important development in the 2000s, inspired by Asian American studies, was the emergence of comparative studies within transnational and diasporic paradigms and a shift among many researchers toward referring to the field as Chinese diaspora archaeology. These approaches recognize the significance of multiple simultaneous physical and psychological connections and identities migrants maintain between home

Overseas Chinese Archaeology, Fig. 5 Chinese and non-Chinese kitchen wares in a reconstructed Chinese home, Barkerville, British Columbia

Overseas Chinese Archaeology, Fig. 6 Chinese cemetery in Hilo, Hawai'i

and host countries and with Chinese diaspora communities elsewhere. In Voss and Williams (2008) and in her dissertation, Kraus-Friedberg adopts a transnational approach to interpreting Chinese, Japanese, and Filipino plantation cemeteries in Hawaii. She argues Chinese migrants constructed unique local identities rooted in both home and host countries by adopting and modifying native Hawaiian burial practices. González-Tennant (2011) draws on diaspora studies in calling for comparative research among overseas sites, both with one another and with their home regions in China, to emphasize the heterogeneity of Chinese communities and the diversity of their experiences abroad. As exemplified in Kraus-Friedberg and others' work, increasing attention has also been directed to Chinese cemeteries and funerary rituals, including cultural persistence and transformation, regional origins of particular rituals, the importance of feng shui, the practice of exhuming and returning remains to the homeland, and bioanthropological studies of human remains (Fig. 6). Work has involved excavation, along with analysis of spatial organization and grave markers, emphasizing the retention of Chinese death rituals and the timing and manner with which they were combined with local Euro-American practices (Chung and Wegars 2005).

A major priority of several Chinatown projects since the 2000s has been community involvement and collaboration between disciplines and institutions, including universities, museums, cultural organizations, government agencies, and resource management firms. One of the best examples is the Market Street Chinatown Archaeological Project, directed by Barb Voss at Stanford University, focused on analyzing and publishing a collection of artifacts from San Jose's Chinatown originally excavated in a resource management context in the 1980s. Another increasingly important component of Chinese diaspora archaeology is self-reflexive studies that critically examine the nature of the field in terms of its objectives, standpoints, and agendas, along with biases, power relationships, and the kinds of research questions scholars are asking (or not asking) (e.g., Wegars 1993; Voss 2005). For example, Fong (2007) explores the role of historic stereotypes of Chinese Americans in the development and current practice of Chinese diaspora archaeology. Similar disciplinary critiques have been offered in Australasia.

In Canada, archaeological research on the Chinese diaspora remains limited compared to the USA and is largely restricted to British Columbia and dominated by graduate student research. The most substantial work includes excavations at a Chinese store and society hostel in the gold mining town of Barkerville and an associated regional settlement survey of Chinese mining sites in the broader North Cariboo District (Fig. 7). Another major research project is a comparative study of Chinese and Japanese salmon cannery workers along the lower Fraser River. Substantial studies have also been done at a Chinese mining

Overseas Chinese Archaeology, Fig. 7 Chee Kung Tong benevolent society hall, Barkerville, British Columbia

community and associated cemetery at Wild Horse Creek Provincial Historic Site, twentieth-century urban cemeteries in Vancouver and Victoria, and the D'Arcy Island Leper Colony in the Gulf Islands. There have also been small-scale urban excavations in Vancouver, Victoria, and Nanaimo (Ross 2015).

The Past Five Years

Over the past 5 years or so, archaeological research on the Chinese diaspora has continued to expand and diversify, filling in regional and thematic gaps and addressing some of the critiques and limitations of earlier studies while increasingly adopting transnational, diasporic, and other theoretical approaches. What follows is an overview of the past half-decade of research organized thematically: Chinatowns, rural and industrial sites, comparative studies, cemetery studies, material culture studies, and topical overviews.

The most active urban research is ongoing work on the Market Street Chinatown in San Jose. Especially valuable are recent studies of botanical remains, artifact residues, and wooden artifacts, all understudied in Chinese diaspora archaeology. Voss et al. (2015) analyzed residues from ten glass medicine bottles recovered from Market Street, revealing the presence of mineral-based stone drugs common to traditional Chinese medicine in seven of them, highlighting the importance of such remedies in the healthcare regimens of Chinese migrants. In a broader study, Cummings et al. (2014) report on an intra-site comparison of botanical and other plant-based food remains from merchant households and tenements. Both household types consumed a variety of fresh fruits and vegetables, but there was variability in the variety of cereal grains, legumes, vegetables, fruits, and nuts between households that may relate to social class and/or occupation. Seiter et al. (2015) studied wood artifacts from Market Street, including taxonomic identification to explore trade patterns, analysis of structural timbers to elucidate Chinatown's built environment, and analysis of portable objects to shed light on work, recreation, and dining. In the most wide-ranging study to date, Kennedy's (2016) research combines botanical and faunal data to focus on relationships between food and identity and how food choices connected people to one another and to specific places. He argues that certain shared food practices that crosscut class differences between merchants and laborers aided in combating racist exclusion and promoted community cohesion. Kennedy draws on transnational

approaches to explore how the complex flow of people, goods, and ideas throughout the Pacific influenced food practices and uses faunal data to link Market Street to fisheries across North America and China.

Recent research has also been conducted at several other Chinatowns. Fong (2013) presents a multidisciplinary study of the Chinese community in Isleton, California, drawing on archives, oral histories, and archaeological data, along with an interpretive approach rooted in racial theory and an explicit rejection of assimilation-based interpretive models. Addressing Mullins' call for greater attention to race among archaeologists, Fong's analysis explores everyday life in the community and identifies structural racism in American society rather than assimilation pressure as a key force influencing material practices among community members. Sunseri (2015) presents archaeological data from Chinese and Paiute neighborhoods at Mono Mills in California's mining frontier suggesting evidence for material interactions between ethnic communities. Such evidence includes pine nuts and obsidian, of probable Native American origin, recovered from a Chinese household, and a Chinese porcelain spoon recovered from the Paiute neighborhood. Though the nature of such relationships remains unclear, Sunseri argues that the data provide evidence for agency among marginalized groups in the context of racial discrimination. In contrast, Porcasi (2016) argues that faunal data from a Chinese laundry in Santa Barbara, California, dominated by pork, provides strong evidence for retention of traditional foods and limited assimilation into local society despite the major economic role the laundry played in the wider non-Asian community. Such research highlights the continued role of acculturation narratives in Chinese diaspora archaeology.

Ongoing research has also addressed a series of rural and industrial contexts, including fishing, mining, and railroad camps across the Western USA and Canada. Ross (2013) presents a comparative study of the everyday material lives of Chinese and Japanese salmon cannery workers in British Columbia, using a theoretical approach rooted in the related concepts of transnationalism and diaspora that he argues is broadly applicable to archaeological studies of long-distance population movements. He uses data from these two labor camps, especially evidence for drinking and dining, to examine how displacement associated with overseas migration and ongoing relations between home and host societies shaped consumer habits and identities of both groups of immigrants in unique ways. Braje and Bentz synthesize previous research and present new findings on late-nineteenth- and early-twentieth-century Chinese abalone fishing camps on California's Channel Islands (Braje et al. 2014; Bentz and Braje 2017). They address topics including results of survey and excavation, descriptions of artifacts and features, and detailed contextual information on the geographic origins of the Chinese fishermen, including how they came to control the fishery and how their products became part of the local, regional, and international economies. Some camps were occupied over time by different ethnic groups exploiting a range of marine species, including precontact Chumash and historic Japanese and European immigrants, reflecting changing land use patterns. Springer (2015) presents three case studies of geochemical and macrobotanical analysis from Nevada, including a rural Chinese mining community near Elko, demonstrating the potential for inter-site comparisons to identify regional trends in health and consumer practices. Privy soil from the Chinese settlement indicates residents were exposed to toxic chemicals like mercury and lead, perhaps from patent medicines, while botanical remains provide data on economic status and availability of consumer goods in remote locations. In one of the most comprehensive recent studies, Merritt (2017) presents a historical anthropology of the Chinese in Montana from the 1860s to the 1940s, interweaving archaeological, archival, and oral history data on known and newly documented sites. Merritt seeks to develop a statewide historic and archaeological context for early Chinese immigrants in Montana while also analyzing the internal structure of the Chinese population and highlighting their contributions to the state's infrastructure and economy. Another major publication is an edited volume of

Historical Archaeology featuring the Chinese Railroad Workers in North America Project Voss (2015b). This project, established at Stanford University in 2012, is an interdisciplinary, transnational project involving researchers in the USA and China, focused on documenting the neglected history of Chinese railroad workers. Papers address sites in California, Utah, Montana, Nevada, and other western states and cover topics including pioneering fieldwork on railroad sites in the 1960s, moral discourses on labor relations, comparisons of railroad construction camps, methods for analyzing ephemeral sites occupied for short periods, multiethnic alliances between railroad workers, Chinese inscriptions on sandstone cliff faces, Asian coins and faunal remains recovered from labor camps, healthcare practices among railroad workers, analysis of skeletal remains from a Chinese cemetery along the railroad, and commentaries on the past, present, and future of archaeological studies of Chinese railroad workers.

Rather than focusing on one or the other, some researchers have sought to compare data from urban and rural settings or interrogate the nature of this divide. For example, Dale (2016) compares data on urban and rural Chinese sites in and around Aurora, Nevada, dating from the 1860s to 1920s, including a series of woodcutter camps, to explore factors influencing the material decisions of their occupants on a local and regional scale. She focuses on the concept of agency in examining how forces internal and external to these communities, including culture contact, identity, and economics, played key roles in decision making, drawing on additional comparative data from the Chinatown in Bodie, California.

Two recent cemetery studies include work by Harrod et al. (2012) on human remains from Carlin, Nevada, dating to the late nineteenth and early twentieth centuries, and Gust's (2016) published report on excavation of 73 Chinese graves dating to the mid- to late-1880s in a historic cemetery in Los Angeles. Harrod and colleagues seek to correlate socioeconomic and political inequality between Chinese and other local populations and activity-induced skeletal changes, including pathology and trauma, related to things like physical labor, accidents, and interpersonal conflict. Gust focuses on a combination of skeletal and material culture data, noting the presence of spiritual offerings, evidence for disinterment that typically left such offerings and things like clothes and personal items behind, and confirmation that women and children were also present among the deceased at a time when the immigrant population was dominated by men.

Although not as common as they once were, material culture studies continue to be an important part of the field. For example, a recent study by Choy (2014) revises our understanding of Chinese ceramics commonly found on overseas sites of the nineteenth and twentieth centuries, based on historical research, travel to ceramic museums and production centers in Southern China, and interviews with ceramics scholars in the homeland. Such revisions contribute to our understanding of design elements, manufacturing origins, reign marks, dining habits, and Chinese language terminology used to describe these wares. Likewise, in their archaeological guide to coins found on North American sites, Akin et al. (2016) devote an entire chapter to Asian coins, covering coins from China, Vietnam, Japan, and Korea and address topics including currency systems, physical characteristics, inscriptions, replicas and forgeries, and non-currency uses of coins in overseas contexts.

Finally, some researchers have sought to explore the wider context of Chinese diaspora archaeology, either through literature reviews, critical assessments of interpretive concepts, syntheses of regional archaeological data, or reconceptualization of the field itself. Ross (2015) reviews the history of archaeological research on the Chinese diaspora in British Columbia spanning the 1980s through 2010s and situating it within the context of the wider discipline in western North America. Molenda (2015) reassesses archaeological approaches to feng shui, arguing that it is not a strict set of rules to be followed and cannot be studied using a checklist approach to determine its presence or absence at a particular site. Rather than something that is present or absent, it is a pervasive aspect of the

landscape. Furthermore, while there are regularities to how Chinese craft cultural landscapes, feng shui should be viewed as a dynamic, culturally informed aesthetic approach to organizing space as it is encountered, varying from one place to the next and incorporating multiple solutions for each unique situation. Kennedy (2017) moves beyond his work on food at the Market Street Chinatown in California, discussed above, to shed light on the Chinese fish trade in North America more broadly, combining archival data on Chinese fisheries and archaeological data from Chinese sites across the West. He concludes that Chinese immigrants continued to consume fish species resembling those consumed in the homeland but acquired them from a range of sources in China and throughout western North America. In a major reconceptualization of the discipline, Voss (2015a) seeks to expand Chinese diaspora archaeology beyond its focus on sites and research resources in North America (and other settler societies) into a transpacific archaeology of the modern world that harnesses the potential of transnational and transdisciplinary research between the USA and China. In doing so, she draws on examples from her work with the Chinese Railroad Workers in North America Project, highlighting research resources and complementary scholarship available in homeland regions of China. This approach is also exemplified in ongoing archaeological research by Voss and colleagues at a home village in China's Pearl River Delta.

International Perspectives

Outside North America, substantial Chinese diaspora archaeology has been done in Australia and New Zealand. Much pioneering research in Australasia focused on goldfields in heritage management contexts and was more a product of an interest in mining sites and landscapes than an explicit interest in Chinese heritage (Lawrence and Davies 2011). The earliest Overseas Chinese archaeology was conducted by Ritchie (1986) at a series of Chinese mining-related sites on New Zealand's Otago goldfields from the late 1970s to mid-1980s in conjunction with hydroelectric development. His dissertation and publications contain a wealth of valuable data on Chinese sites and material culture. Likewise, early work in Australia focused on a Chinese market garden on the Palmer River goldfield in North Queensland. Since Ritchie's studies, only limited archaeological research has been done on Chinese sites in New Zealand, including a series of regional surveys and large-scale excavations at Lawrence Chinese Camp in the Otago region. Mining has remained a prominent focus in Australia, comprising regional surveys and excavation since the 1980s, including Smith's (2006) work on Chinese regional settlement systems in New South Wales.

However, increasing urban archaeology in the 1990s uncovered sites associated with Chinese immigrants in neighborhoods of Sydney and Melbourne (Lawrence and Davies 2011). Since then, Chinese diaspora archaeology in Australia has become increasingly research oriented and diverse both thematically and in terms of site types investigated, ranging from market gardens to fish-curing sites. Studies have addressed issues of social and economic organization, hierarchical settlement patterns, trade networks, consumption patterns, comparisons between urban and rural life, relations with non-Chinese, and religious beliefs and rituals. Particular classes of Chinese sites and features have been the focus of considerable attention as central places in Chinese physical, social, and ritual landscapes, including temples, cemeteries, and stone ovens used to prepare communal meals. Themes include the role of feng shui in the location and orientation of sites and structures, architectural and stylistic analysis of temples, types and uses of ovens, and the role of all of these features in settlement networks.

As in North America, most early work was done in conjunction with resource management and emphasized descriptive and typological studies of Chinese sites and material culture. Most studies also adopted theoretical frameworks emphasizing acculturation and situational adaptation, largely arguing in favor of cultural persistence. However, there has been increasing realization that objects like Chinese and

European ceramics were embedded in complex trade networks, social strategies, and relations of power within and beyond the Chinese community. A number of studies have shown how Chinese combined traditional dining and drinking habits with those of the host society, demonstrating a complex combination of continuity and change. For example, like the Praetzellises in Sacramento, Muir (2008) argues that Chinese in Melbourne used English ceramics consciously as a means of gaining access to opportunities in a white-dominated society, and use of Chinese ceramics had as much to do with obligation and reciprocity as a desire to maintain traditional diet.

A landmark work in the region was Lydon's (1999) study of Chinese in the Rocks neighborhood of Sydney, replacing acculturation with a model of cultural entanglement and exchange and of bounded and static ethnicity with multiple fluid and competing identities. Lydon explored the role of material objects in colonial encounters between Chinese immigrants and those of European descent. In her examination of cultural exchanges between these groups, objects and material behaviors comprise a form of communication that draw on elements of both cultures, which she refers to as "pidgin English." The fluidity of identity means that inherited and adopted objects and practices can be complementary and immigrants can hold multiple simultaneous identities as both Chinese and Australian. As part of her study, she also offered a detailed overview and critique of the field in North America and Australasia.

Since the 1990s, scholars and heritage organizations in Australia have developed a series of studies of Chinese heritage resources. These include a thematic survey of Chinese sites in the country that comprised a historical overview, an annotated bibliography, and a state-by-state analysis of recorded sites and investigations, plus a national database of sites and a guide for finding and assessing Chinese heritage places (Casey and Ritchie 2003). Unlike the USA, Chinese diaspora archaeology in Australasia has had a significant influence on the larger discipline with respect to themes like race and ethnicity and is discussed in depth in Lawrence and Davies' (2011) overview of historical archaeology in Australia. Likewise, there has long been a close relationship between archaeologists, historians, museum personnel, and community members, including joint conferences and publications. One such conference resulted in a thematic volume of *Australasian Historical Archaeology* on Chinese sites in Australia and New Zealand (Casey and Ritchie 2003). Besides an overview of the field, it includes papers on identifying Chinese alluvial mining and other sites, along with studies of Chinese ceramics, temples, cemeteries, and a summary of Chinese archaeological sites, artifact repositories, and archives in North America and Australasia.

In the past half-decade, there have been a series of new studies in Australia, and to a lesser degree New Zealand, addressing aspects of Chinese diaspora archaeology in general or presenting individual case studies. Burke and Grimwade (2013) review the history of archaeology of Chinese immigrants in Far North Queensland. They note that much of it has been driven by resource management projects, producing data of variable quality and comparability that is skewed toward urban centers, and recommend more research-oriented studies. Nevertheless, they are able to draw some generalizations relating to drinking and dining behavior, which exhibit a trend toward use of imported Chinese ceramic tableware contrasted with a marked preference for European alcohol. This pattern resembles what Ross (2013) observed for Chinese and Japanese cannery workers in British Columbia, and Burke and Grimwade suggest that this may reflect use of these two material practices in different ways in the construction of individual and collective identities. Byrne (2016) argues in favor of a transnational approach to interpreting the material heritage of Chinese migration to Australia in the nineteenth and twentieth centuries. He proposes the concept of a "heritage corridor" as a more accurate representation of the back and forth movement of people, objects, ideas, and currency than the one-way nation-based narratives of migrant arrival and settlement. He pays close attention to migrants' continued ownership of property in the homeland and the role of

remittances in the construction of homes, schools, temples, infrastructure, and other aspects of the built environment.

Several recent studies in Australia and New Zealand draw on archaeological data to explore the lives of market gardeners. Adamson and Bader (2013) examine how Chinese market gardener Chan Dah Chee, living in Auckland away from established Chinese communities and networks, survived and thrived through strategic use of European material culture in traditional Chinese ways and by creating social and economic bonds with influential non-Chinese families. In this sense, the authors draw from interpretive themes and approaches pioneered by Mary and Adrian Praetzellis in California in the 1980s and 1990s. Similarly, Boileau (2013) focuses on material objects to highlight the daily lives and social interactions of Chinese market gardeners in Australia and New Zealand, but, rather than an entire assemblage of artifacts, focuses on four representative objects. Two of the objects are archaeological, a garden rake and European ceramic tableware, while the other two (an oil engine and a watch chain) are in museum or personal collections. Themes addressed through these items include agricultural practices, labor organization and technological change, and interactions with Europeans. Like Adamson and Bader, Rains (2013) emphasizes social and economic relationships between Chinese and European communities, drawing on data from the frontier community of Cooktown in North Queensland. He shows how Chinese were integrated through a series of complex negotiations into the town's socioeconomic fabric, with both Chinese and European communities controlling key economic niches that made them dependent on one another, rather than antagonistic competitors that relegated Chinese to the margins. This is evident, for example, in archaeological evidence that shows that Chinese residents occupied some of the best gardening sites in town.

Recent years have seen publication of two major monographs on Chinese archaeology in Australia, Esposito's (2014) study of imported Chinese ceramics and Bowen's (2012) research on the Chinese role in Victoria's colonial fishing industry. Esposito compares ceramics from a series of Chinese gold mining camps in New South Wales spanning the mid-nineteenth through early twentieth centuries, focusing on Chinese supply networks, the role of ceramics in everyday life, use of Western-style ceramics by Chinese miners, and comparisons with local non-Chinese sites. Her study includes detailed descriptions of her datasets and innovative compositional (electron microprobe) analysis of Chinese ceramic sherds to identify their manufacturing origins in China. In contrast, while Bowen addresses the wider history of commercial fishing in Australia during the late nineteenth century and the dominant role of Chinese immigrants in this industry, his archaeological analysis focuses on a single Chinese fish-curing camp in Victoria occupied between the 1860s and 1907. His results address Chinese entrepreneurship, interactions between Chinese and Europeans, inequalities between Chinese merchants and laborers, and the structure and internal workings of the camp itself.

Future Directions

To date, most research on Chinese diaspora sites remains centered on the Western USA and Canada, and similar regionalism exists in Australasia. There is considerable need for expansion into other regions and countries in the Americas, Asia, Europe, and Africa where Chinese migrants settled, as well as the homeland itself, as advocated in Voss' transpacific approach. There is also need for more comparative studies of Chinese communities in a range of contexts and with other Asian and non-Asian diasporas and ethnic groups, though recent research is beginning to fill this gap. Detailed comparisons between North America and Australasia would aid in understanding the relationship between local circumstances and broader international patterns of diasporic population dispersal, and continued efforts by Australian researchers to engage the North American literature are a major step in this direction. The field would also benefit by including research on the Asian diaspora more broadly, including migrants from Japan, Korea,

Overseas Chinese Archaeology, Fig. 8 Chinese medicine bottles recovered from a salmon cannery near Vancouver, British Columbia

the Philippines, and elsewhere, all understudied by archaeologists.

Material culture studies have focused primarily on descriptive typologies, and much less attention has been granted to the cultural origins, shifting meanings, and social and economic contexts in which these objects were produced, marketed, and used. More work like Esposito's is also needed on materials analysis like elemental characterization to refine our understanding of the regional origins, manufacturing technologies, dating, and distribution networks of ceramics, bottles, and other artifacts commonly found archaeologically (Fig. 8).

As the field matures, it is necessary to continue pursuing collaborative studies with local communities, organizations, and institutions and with scholars in related disciplines, as active participants in research design, methods, interpretation, and dissemination of results. Research must also continue to integrate oral history, archival research using Asian language sources, and recent developments in Asian diaspora studies with the results of archaeological analysis. For the field to maintain contemporary relevance, archaeologists must be increasingly self-reflexive about the assumptions and agendas underlying their research, along with the interests it serves and its implications for living communities. Of particular value would be more substantial development of relationships with scholars in China, as Voss and colleagues are currently doing, to pursue archaeological and ethnohistorical research on everyday life in the nineteenth and early twentieth centuries. Such data would provide a more nuanced context for interpreting overseas sites similar to ongoing work in Africa and Ireland, not only as a model of life prior to emigration but to understand changes influencing transnational migrants maintaining ongoing relationships with the homeland.

In the 2008 thematic volume of *Historical Archaeology*, Voss and Allen argued that Chinese diaspora archaeology was still an emerging field and faced three major challenges to its further development. They include a continued need to (1) shift from descriptive reporting to problem-oriented research that addresses pluralistic, multiethnic sites and issues of power and race, (2) move away from acculturation and develop alternative models of intercultural contact that account for complex relationships between immigrants and the host society, and (3) overcome the Orientalist tendency to draw fundamental, stereotypical distinctions between Eastern and Western culture that homogenize variability. To meet these objectives, the authors call for research that is multistranded, multisited, multilingual, multi-scalar, and multidisciplinary. These five "m's" encapsulate the future of the field, and with major strides evident in the past decade since this volume was published, it is poised to make a major impact in historical archaeology and the broader discipline as a whole.

Özbaşaran, Mihriban

Ece Birçek
Istanbul, Turkey

Basic Biographical Information

Mihriban Özbaşaran was born in Turhal, located in Tokat City, Turkey. She graduated from Kadıköy Anatolian High School in 1975 and started her studies at Istanbul University's Classical Archaeology Department in 1975. She graduated with an undergraduate thesis titled "House Types of Continental Greece: Neolithic, Early Hellas, Middle Hellas Ages," supervised by Prof. Dr. Aşkıdil Akarca, while taking the subsidiary certificate programs including prehistory, Greek language, and literature. Özbaşaran finished her M.A. dissertation titled *Structural Characteristics of the Early Chalcolithic Architecture of Tülintepe* in 1984. She was assigned as an assistant in 1985 in the Prehistory Department of Istanbul University. Her Ph.D. studies, which she started in the same year, were finished in 1994 with a dissertation entitled *Place of Tülintepe Architecture in Chalcolithic East and Southeast Anatolia*. Özbaşaran was promoted as Assistant Professor in 2000 and Professor in 2008.

Major Accomplishments

During Özbaşaran's undergraduate studies, she participated in excavations such as those at Perge, led by Prof. Dr. JaleİnAn, in 1977, followed by Aizonai, under the direction of Prof. Dr. R. Naumann from 1978 to1979. Özbaşaran began as a student at Domuztepe, supervised by Prof. Dr. Halet Çambel, and continued her work as an M.A. scholar and then as a Ph.D. scholar.

Özbaşaran served as the field director at the Yarımburgaz excavations led jointly by Prof. Dr. Trust, from the University of California, and Prof. Arsebük. She also participated in the Aşıklı Höyük excavations led by Prof. Dr. Ufuk Esin. Özbaşaran worked as a team member on numerous studies such as the Gournia/Girit Survey Research Project conducted by Prof. Dr. L.V. Watrous from Buffalo University.

Özbaşaran directed excavations in Neolithic Musular in Aksaray, Cappadocia from 1996 to 2004 and Neolithic Akarçay Tepe in Birecik, Urfa, leading international teams consisting of specialists and archaeologists. She also conducted the Istanbul area excavation at Çatalhöyük, under the direction of Ian Hodder from Stanford University, from 2005 to 2008.

Özbaşaran is the leader of the Aşıklı Hoyuk (Aksaray, Central Anatolia) Excavation, Research, Conservation and Exhibition Project, which began in 2006. Her key lecture subjects are the history of archaeology and scientific approaches; theoretical archaeology; experimental archaeology; cultural evolution in prehistory; complex societies; and key concepts of prehistory and prehistoric cultures of Cyprus. Her area of expertise is mostly focused on the neolithization process of central, east, and southeast Anatolia between the ninth and seventh millennia. She continues to study neolithization models, developmental differences, and similarities between the two regions in question.

In recent years, Özbaşaran has been leading the project of Aşıklı Höyük in ethnoarchaeology, experimental archaeology, and cultural heritage management content.

Özdoğan, Mehmet

Ece Birçek
Istanbul, Turkey

Basic Biographical Information

Mehmet Özdoğan was born in Istanbul, Turkey, in 1943. He graduated from İstanbul University's Faculty of Literature Prehistory Department in 1969. He was awarded his M.A. on the basis of his dissertation, titled *Dating and Evaluation of Pottery and Small Finds of Kumtepe from 1934 Season*, in 1970 and began to serve as an unsalaried assistant with the Department of Prehistory, Istanbul University, until 1975. He became Dr. Assistant in 1979 on the basis of his Ph.D. dissertation titled *Evaluation and Dating Problematic of the Fikirtepe Small Finds from the Years Between 1952 and 1954*. He was promoted to the post of Assistant Professor in 1985 and Professor in 1994. Professor Özdoğan spent many years as Head of the Archaeology Department at İstanbul University. He is a member of numerous scientific institutes and groups and was elected as a foreign member of the American National Academy of Sciences in 2005.

Major Accomplishments

From the beginning of his undergraduate years, Mehmet Özdoğan participated in numerous archaeological excavations and projects, including the Çayönü excavations undertaken by İstanbul and Chicago Universities. In these excavations he worked primarily as field director and later as project director. As well as being the general director of Archaeological Survey Research of Lower Euphrates Project organizing by Middle East Technical University (ODTÜ), Mehmet Özdoğan was the field director of excavations at Keban, Tepecik, Tülintepe, and Degirmentepe.

Mehmet Özdoğan's major fields of study are the origin and diffusion of village, life based on food production in Neolithic period, cultural relations between Southeast Europe, Aegean and Anatolia, geoarchaeology, politics and history of archaeology, and cultural heritage management. His contributions to Turkish archaeology include the development of a new model for archaeological survey research and research investigations into diffusion of the first food-producing groups from Anatolia to Southeast Europe.

Mehmet Özdoğan also made a major contribution to archaeology in Turkey through developing the concept of a cultural sector and by developing cultural inventories for the Turkish Academy of Sciences (TÜBA). In 2001, he directed a pilot project on cultural inventories in the region of Birecik-Suruç, Şanlıurfa, as a part of the TÜBA-TÜKSEK (Turkey's Cultural Sector) Developing with Culture project.

Özgüç, Nimet

Ece Birçek
Istanbul, Turkey

Basic Biographical Information

Nimet Özgüç was born in Adapazari in 1916. After graduating from Ankara Girls' High School, she was among the first students of the newly established Faculty of Languages, History, and Geography of Ankara University, along with her future husband, Tahsin Özgüç. She studied from 1936 to 1940 and, after completing her education, was assigned to the Archaeology Department as an assistant. After receiving her Ph.D. dissertation titled *Anatolian Stamp Seals* in 1943, she was promoted to assistant professor in 1949 and then professor in the Protohistory and Near Eastern Archaeology Department of Ankara University in 1958.

Major Accomplishments

Nimet Özgüç participated in the excavations of Ankara Roman Bath, Çankırıkapı, and Temple of Augustus carried out by Prof. Dr. H.H. von der

Osten and Prof. R.O. Arık. She was a member of the team which carried out the Dündartepe, Kavak, Kaledoruğu, and Tekeköy excavations in 1941, and the Elbistan Karahöyük excavations and survey studies in Elbistan plain together with Tahsin Özgüç. Her work on the separation and development of Assyrian trade colonies' seals and seal impression styles helped to clarify the development of the art style of Anatolian history of the period, the Mesopotamian Old Assyrian period*s*, and Old Babylonian period.

Nimet Özgüç also participated in the excavations of Kayseri Frakdin in 1954 and Erzincan Altıntepe in 1959. She led the Acemhöyük excavations which she started in 1962 and continued until 1989. During the Acemhöyük excavations, two of the best-preserved monumental palace buildings in Anatolia were revealed, and it emerged that the settlement was the center of a local kingdom in the Assyrian trade colonies period.

Nimet Özgüç investigated the period from the Byzantine to Iron Age within the excavations in Niğde Tepebağları that she led. From 1978 to 1989, as a part of the Middle East Technical University's Lower Euphrates Project, she conducted the Adıyaman-Samsat-Huyuk excavations which were going to be inundated by the Atatürk Dam reservoir. In Samsat, which is one of the largest and highest mounds of Anatolia, she found evidence of a time period ranging from the Chalcolithic to Seljuk. She published papers concerning the Sumeysat of Seljuk period; Hellenistic and Roman periods; Samosata, the capital city of Commagene Kingdom; and Kummaha and Hahhum of the Iron and Bronze Ages.

Nimet Özgüç served as a member of the Ministry of Culture High Council of Real Estate Antiquities and Heritage in 1984. Following her retirement the same year, she continued to work in excavations that she conducted and resumed her scientific activities by publishing books and articles.

Özgüç received awards including the G. Bude Medal of College de France (1980) and the "Woman of the Year" award of the Turkish Women's Union on Science field. She conducted courses and seminars as a guest lecturer at Munich, London, Saarbrücken, Marburg, Princeton, Columbia, Yale Universities, and Bryn Mawr College. In addition, she served as an ordinary member of the German Archaeological Institute (1979), honorary foreign member of the Archaeological Institute of America (1994), honorary member of Turkish Historical Society (1995), and honorary member of Ancient Historical Sciences Istanbul (1995).

Özgüç, Tahsin

Ece Birçek
Istanbul, Turkey

Basic Biographical Information

Tahsin Özgüç was born in Kýrcaali, Bulgaria, in 1916. He was one of the first students of the newly established Faculty of Languages, History and Geography at Ankara University in Turkey. He studied archaeology, history, dead languages, and their cultures under some of the esteemed scientists of the period such as Şevket Aziz Kansu, Şemsettin Günaltay, Hans Henning von der Osten, Hans Güstav Güterbock, Benno Landsberger, and Georg Rohde. He was awarded a Ph.D. in archaeology in 1942 based on his thesis, which was titled *Anatolian Idols in Prehistory*. He was appointed as an Assistant Professor at Ankara University in 1946 and became a Professor in 1954.

Major Accomplishments

In 1940, Tahsin Özgüç began to carry out excavations which were going to last over 2 years in the Samsun region (Dündartepe, Tekeköyve, Kaledoruðu). This work was conducted with his colleagues Kýlýç Kökten and Nimet Özgüç. In 1945 Özgüç undertook excavations of two tumuli together with Mahmut Akok. These tumuli were in the construction area of the Mausoleum of Mustafa Kemal Atatürk in Anýtkabir. Özgüç was appointed as an Assistant Professor at Ankara University after completing his habilitation thesis titled *Burial Customs of Anatolia in Prehistory* in 1946. In that same year he carried out the excavations of Sivas Maltepe and Sivas Tower.

In 1947 Tahsin Özgüç was elected as a member of the Turkish Historical Society, along with two other important scientists, Aydýn Sayýlý and Halil Ýnalcýk. Dr. Özgüç conducted excavations at Fraktin (Develi, Kayseri) and Karahöyük (Elbistan-Maraş) in the same year. In 1948 he began excavations at Kanis-Nesa (Kayseri). These excavations were to continue over for his lifetime, for 58 years.

After he became a Professor in 1954, Tahsin Özgüç's responsibilities grew. In that year he undertook the Kültepe excavations himself while simultaneously directing other excavations in different settlements. In subsequent years, he examined the different periods of Anatolian cultures and published his evidences in a systematic manner. He undertook excavations at an Early Bronze Age settlement area and cemetery in Horoztepe (Erbaa, Tokat) in 1956; at Altýntepe (Erzincan), which had remarkable architecture and small finds, in 1959–1966; at Kululu (Kayseri), which was the center of one of the Late Hittite kingdoms Tabal with particular sculptures and hieroglyphic-inscribed lead plates, in 1967; at Ma°at Höyük (Zile, Tokat), one of the few cities located outside of the center Boðazköy that had Hittite archives, from 1973 to 1983; and at Kazankaya (Çekerek, Yozgat), at a cemetery of the old Hittite which highlighted the different periods of Anatolia, in 1976.

Tahsin Özgüç was an internationally recognized scholar. He lectured in the Institute for Advance Study, Princeton University, in 1962–1963; Universität des Saarlandes in 1964; and at Universität München in 1975–1976, 1978–1979 and 1980–1981. Dr. Özgüç conducted

seminars and conferences in various universities throughout Europe and the USA. He was awarded the Order of Merit by the Federal Republic of Germany, the Order of the Rising Sun of Japan, the National Order of the Crown of Belgium, and the Collége de France Medal.

P

Pacific Islands: Finding the Earliest Sites

Mike T. Carson[1] and Hsiao-chun Hung[2]
[1]Micronesian Area Research Center, University of Guam, Mangilao, GU, USA
[2]Department of Archaeology and Natural History, The Australian National University, Canberra, ACT, Australia

Introduction

The character and date of the earliest settlement of the remote Pacific Islands remains an important research objective. Tracing human origins in "Remote Oceania" reveals a series of west-to-east migrations, ultimately from southern coastal China before 6,000 years BP (Bellwood et al. 2011). In the far west of Micronesia, the Mariana Islands have become known as the home of the oldest archaeological sites of Remote Oceania, dated 3,500–3,300 years BP (Fig. 1).

We are only now achieving some clarity on where to find sites, in a manner that conforms to CRM constraints. The local governments consider excavations to be destructive to cultural heritage resources and harmful to the natural environment. Archaeological excavations are therefore undertaken only in strict compliance with government regulations, which are not always conducive to archaeological visibility. The normal procedures use *shovel tests*, holes 10–20 m apart dug the size of a shovel blade and sieved through a 6 mm mesh, to find sites, and *test pits*, 1 × 1 m in plan taken down by trowel, to investigate them. Monitoring of a machine-dug trench has become standard procedure for archaeological resource management in beach settings.

Key Issues/Current Debates/Future Directions/Examples

Survey

Nearly all sites in the Marianas are found through *surface reconnaissance*, walking at close intervals (usually 5 m) through the dense jungle, sometimes augmented by transects of *shovel testing* where the ground visibility is particularly difficult. This approach works well in areas with little or no soil development, where site remnants are easily accessible. In fact, most island terrain fits into this category, bearing perhaps 20–30 cm of rocky silt or clay directly over solid bedrock. Using little or no excavation, this strategy has been successful for mapping and recording sites of the more recent time period, roughly within the last 1,000 years. Megalithic house pillars and capitals (locally called *latte*) mark most residential sites. Broken pottery is littered almost everywhere, along with lesser amounts of stone and shell adzes and other such durable tools.

Pacific Islands: Finding the Earliest Sites, Fig. 1 Island-wide terrain model of Guam showing (**a**) conditions 3,500–3,000 years BP and (**b**) modern conditions (Modified from Carson 2011)

For the most ancient sites, dating to 3,500–3,300 years BP, the best chance of finding a preserved archaeological deposit is to search in the beach sand. These locations fortuitously match expectations of where the earliest islanders lived, near productive crop-growing soils and bountiful coral reef ecosystems. The beaches as seen today, however, are recent geological formations. The ancient sea level stood 1.8 m higher than today, plus the earliest sites are at least 1–2 m beneath today's sandy beaches and 100 m or farther inland from modern shorelines. These circumstances teach us two things. First, the coastal terrain has been transformed substantially since the time since the sites were first inhabited. Second,

Pacific Islands: Finding the Earliest Sites, Fig. 2 Setting of 3,500–3,300 years BP beach site at Ritidian, Guam, now more than 100 m from modern shoreline and 2.5 m beneath the surface

exploratory survey for the most ancient sites cannot rely on surface finds, and researchers must dig deeply in locations that may not appear immediately obvious.

Taking into account these formation processes, a paleo-*terrain model* can be used to depict the approximate coastal topography at the time when the oldest sites were inhabited (Carson 2011). The model has been continually refined by *test pits* and trenches that give precise locations, depths, and dates of ancient sedimentary layers, whether or not they contain archaeological materials. The most thorough work has been in Guam, the largest and southernmost of the Mariana Islands.

Excavation

At Ritidian on Guam, dozens of small test pits, each 1 m by 1 m, were dug at 10-m intervals throughout an area targeted by the paleo-terrain model. The most ancient deposit was found only in one of these test pits, meaning that the original site covered a rather small area less than 20 m by 20 m in total. The deepest cultural layer was buried more than 2.5 m deep and more than 100 m from the present shoreline. The ancient shoreline context was dated 3,500–3,300 years BP by radiocarbon. Exceptionally thin (1–2 mm) red-slipped pottery fragments were refitted, representing 10–20% of two different small bowls or jars, plus more than 55% of another shallow open bowl. The oldest site layer at Ritidian was sealed beneath a zone of 1 m of hardened beach sand (calcrete) that solidified after the site had been buried, creating a barrier that few archaeologists would attempt to breach. The excavation required chiseling of large solid blocks of calcrete, later dissolved in mild (5%) acid and sieved through half-mm wire mesh for full recovery of the constituent artifacts and midden. Beneath the calcrete, the loose beach sand was removed by trowel and sieved through half-mm mesh for consistent recovery (Fig. 2).

The most thoroughly studied early period Marianas site has been on the southern coast of Tinian, 100 m inland from the famous megalithic *latte* ruins of the House of Taga. An excavation slightly larger than 90 sq m here proceeded by hand troweling of *stratified layers*, each internally divided into *arbitrary levels* 10 cm thick. This strategy uncovered an arrangement of post-molds, hearths, and other features of an ancient living floor dated about

Pacific Islands: Finding the Earliest Sites, Fig. 3 Arrangement of post-molds, hearths, and other features in ancient living floor 3,500–3,400 years BP, 100 m landward from House of Taga, south coast of Tinian (Modified from Carson 2016)

3,500–3,400 years BP (Fig. 3). Among 30,000+ earthenware pottery fragments, more than 150 exhibited finely impressed, stamped, and incised decorations on a red-slipped surface. Chert adzes and flaked tools, shell beads and pendants, fishing hooks, shellfish remains, and bones of fish, turtle, and birds completed the assemblage.

Pacific Islands: World Heritage

Christian Reepmeyer and Geoffrey Clark
Archaeology and Natural History, The Australian National University, Canberra, ACT, Australia

Introduction

Pacific cultural heritage research has taken an active role in reshaping notions of cultural significance that has been recognized by UNESCO. Acknowledging the importance of associative cultural landscapes, first applied to the Tongariro National Park, New Zealand, in 1993 and Ulu*r*u-Kata Tju*t*a, Australia, in 1994, culminated in the 2008 inscription of the "*Chief Roi Mata's Domain*," Vanuatu, into the World Heritage List (UNESCO 2010).

These advances in Pacific cultural heritage research do not hide the fact that Independent Pacific Island Nations (referred to here as IPIN) are underrepresented on the World Heritage List. The uneven distribution of World Heritage sites globally is exemplified by the presence of only 13 sites in the wider Pacific area and only five sites nominated by IPIN. Below is a list of World Heritage properties located on Pacific Islands (standing 2011).

Key Issues

The strong underrepresentation of cultural sites has been a matter of discussion since the mid-1990s (UNESCO 1994) and resulted in the "Filling the Gaps" – World Heritage Action Plan (ICOMOS 2005) and the World Heritage – Pacific 2009 Programme for capacity building in the region (UNESCO 2004). The plans represent a partial success in that since its launch in 2002, nine of 14 IPIN (including New Zealand and Papua New Guinea) have submitted properties to the World Heritage Commission and in total 39 properties have been registered on the Tentative List. Consequently, there has been an increase in properties inscribed on the World Heritage List; six sites have been inscribed since 2003, although these include the property "*Lagoons of New Caledonia: Reef Diversity and Associated Ecosystem*" in a French overseas territory and the "*Papahānaumokuākea*" property in the US state of Hawaii.

Looking at the representation of cultural sites on the World Heritage List, it is apparent that the usual four-to-one ratio of cultural to natural sites internationally (currently 725 cultural, 183 natural, and 28 mixed properties) is significantly different in the Pacific, where the cultural–natural site ratio is one to four. This ratio might relate to the status of several islands, such as being a territory of one of the Western developed countries USA, UK, or France (Table 1) or being of interest to international nongovernmental organization such as the World Wildlife Fund for Nature and Conservation International, emphasizing on environmental preservation rather than indigenous cultural heritage protection (e.g., "*East Rennell*," Solomon Islands). It has also been argued that the lack of monumental architecture present in the archaeological record of past societies in the Pacific is a factor in the underrepresentation of Pacific cultural heritage on the World Heritage List. Non-monumental cultural heritage is dominant in the Pacific in comparison to the number of built structures in, for example, Europe; however, there are several prehistoric and historic sites with monumental architecture present in the Pacific Islands, such as "*The Ancient Capitals of the Kingdom of Tonga*" in Tonga, "*Nan Madol*" on Pohnpei, the "*Pulemelei Mount and associated stone villages*" in Samoa or the earthwork terraces ("*Ouballang ra Ngebedech*") in Palau, none of which is currently inscribed into the World Heritage List.

[a]*C* cultural site, *N* natural site, *M* mixed site. ***Italic***: properties nominated by Independent Pacific Island Nations (IPIN)

The move by UNESCO to include cultural landscapes into the Outstanding Universal Value (OUV) criteria acknowledges the long-term dominance of monumental sites and the underrepresentation of cultures whose heritage is associated with non-monumental sites on the World Heritage List (Fowler 2003, 2004). This is particularly important for IPIN where a large number of properties (26 out of 52 sites on the WH and Tentative Lists) have a significant cultural landscape component, for example, "*Sigatoka Sand Dunes*" in Fiji, "*Rock Islands – Southern Lagoon Management Area*" in Palau, or "*Manono, Apolima, and Nuulopa Cultural Landscape*" in Samoa. Smith and Jones (2007) and Lilley (2010) recently defined key themes for 13 organically evolved relict and associative cultural landscapes on Pacific Islands in two ICOMOS thematic studies. Early maritime colonization and settlement patterns, social organization of traditional land uses in marginal environments, and seascapes are important research objectives in Pacific archaeology that also have significant cultural heritage values that are frequently "non-monumental."

The two thematic studies also identified a series of properties, including one transboundary (*"Yapese Disk Money Regional Sites*," Federal States of Micronesia/Palau) and one serial site ("*Lapita Pottery Archaeological Sites*"), with OUV in the Pacific. Nonetheless, only three of the properties mentioned in these studies ("*Bikini Atoll Nuclear Test Site*," "*Kuk Early Agricultural Site*," and "*Chief Roi Mata's Domain"*) have been inscribed into the World Heritage List, with multi-jurisdictional difficulties hindering progress in the nomination of transboundary/serial sites.

Current Debates

Seven decades of intensive archaeological research in the Pacific have identified a reasonable number of prehistoric sites with OUV, so why are IPIN underrepresented on the World Heritage List? One major factor in the lack of progress in gaining international recognition for Pacific cultural heritage sites, and consequently their protection, is the limited human resources available in most IPIN for the lengthy and increasingly complicated task of coordinating a successful nomination file for assessment through ICOMOS, IUCN, and UNESCO. It appears that efforts to address the underrepresentation of IPIN sites on the WH List are tempered by a real concern that many IPIN do not have the resources to effectively manage and

protect significant heritage sites. As a result, nomination files submitted by IPIN are likely to be cautiously scrutinized to determine whether the resources and expertise for cultural site management exist. This is appropriate, but an obvious danger is that the desire to reduce imbalance in the WH List by encouraging IPIN to nominate sites is not matched by practical support to increase the heritage expertise of IPIN to a necessary level. Rejection of IPIN WH site nominations due to a perceived absence of heritage capacity would likely result in the skewing of WH site representation in a different direction: a higher representation of sites on the WH List from Pacific Islands which have significant relations with developed nations from their current or former status as an overseas territory/collectivity (France, UK, Australia, Chile), state (US), protectorate (Germany) or free association compact (US, New Zealand). Such a trend is already apparent in the 13 World Heritage properties on Pacific Islands with 62% submitted by developed colonial nations.

In addition to a lack of human resources, many IPIN are still developing their heritage capacity with limited legal protection of heritage sites at the local and national level and incomplete cultural site registers. This is particularly important for the nomination of cultural landscapes which generally cover a large area and include numerous archaeological features many of which have not been surveyed/tested by local and international heritage specialists. This has implications for developing a comprehensive conservation management plan, which is now a standard requirement for the successful nominations of heritage properties.

A way forward for IPIN is to assemble networks of local communities, external and local archaeologists, anthropologists, and other heritage experts. This is likely to be a key strategy for IPIN wishing to produce World Heritage cultural site nominations as shown in the recent successful nominations of three cultural properties from IPIN (Wilson et al. 2009). One positive outcome of such an approach is that it allows knowledge about the *World Heritage Convention* (1972) and WH nomination process to circulate through IPIN government and community organizations and it involves close partnership between the local community and archaeologists/heritage experts.

Participation of local communities and traditional landowners in the nomination process, particularly the provision of traditional knowledge and the management of sites, is actively encouraged by the World Heritage Convention (UNESCO 1972: §14) and by UNESCO (Asia) in the Hoi An Protocols (UNESCO (Asia) 2009). The recognition that many heritage sites in the Pacific are embedded in the cultural traditions of local communities and the relationship between a site and the local community requiring specific consideration in the management plan is an important advance in cultural heritage practice.

UNESCO is by definition an international body of independent nation states, and only federal organizations (State Parties) are able to submit nomination files for inscription. The process of submitting nomination files has significant implications for IPIN where access rights to heritage sites are largely determined through traditional structures. Uncertainty about the impact of World Heritage nomination to access and stewardship of heritage sites occasionally culminates in legal procedures, where traditional owners seek clarification about the ownership of sites. In these cases, external experts can have an important role in mediating conflicting interests for the benefit of conserving heritage sites for future generations. To avoid legal conflict about sites and resources, it is necessary to properly inform local stakeholders about the purpose and effects of property inscription on cultural practices and economic development during the early planning stages of World Heritage nomination. An additional means of informing stakeholder could be the inclusion of local leaders of World Heritage properties as national representatives to annual ICOMOS/IUCN or UNESCO meetings.

Future Directions

World Heritage practice in Pacific Islands is only at its beginning. In the last decade, the exposure of local communities to international cultural heritage concepts and conservation practices has led to the desire to have their cultural heritage

recognized at the international level, which in turn increases the necessity of protecting IPIN heritage sites. This grass roots approach to cultural heritage management deserves to be supported by the international community.

Pacific Ocean: Maritime Archaeology

Jason T. Raupp
Program in Maritime Studies, East Carolina University, Greenville, NC, USA

Introduction

The Pacific Ocean is the largest in the world. Within its vast expanse are thousands of islands which have a rich history of human interaction that stretches back for millennia. Though the distance and the time required for successful crossings created difficulties for seafarers, an understanding of the winds and currents allowed it to be used as a highway (Van Tilburg 2011: 588). Indigenous peoples have inhabited even the most remote parts of the Pacific

for centuries; they constructed villages, navigated and traded between islands, and harvested the marine resources they needed for survival. Europeans and Western cultures used the Pacific Ocean for activities such as exploration, colonization, resource extraction, and trade, each of which has left an indelible mark on the cultures and environment of the region. For many years maritime archaeological projects have been conducted around the Pacific Ocean, and their results have provided unique insights into the human interaction with and within the ocean.

Definition

The area encompassed by the Pacific Ocean is so expansive that geographers use the divisions of South, Central, and North Pacific when discussing the different regions. The greatest density of the islands exists in its central and southern parts, and cultural groups have inhabited these areas for thousands of years. For the purpose of this entry, the area that will be discussed is Oceania. Oceania can be defined as the islands of the southern, western, and central Pacific and includes Melanesia, Micronesia, and Polynesia.

Historical Background

Archaeologists and linguists generally agree that the colonization of the Pacific was a two-pronged movement that began approximately 3,500 years ago (Bellwood 1979: 282; Russell 2009: 63). The first phase involved the settlement of the western Micronesian island groups of Palau, the Marianas, and possibly Yap, and the second involved an easterly movement through Melanesia to western Polynesia, eastern Micronesia, and later the Hawaiian Islands and New Zealand (Russell 2009: 63). Once established on the various islands, complex and distinct cultures developed which were manifested socially, linguistically, and technologically. The connection to the sea was tantamount to these societies, and assemblages of material culture associated with this relationship have been archaeologically documented.

The final phase of Pacific colonization was signaled by the appearance of Europeans within the last 500 years (Lilley 2006: 5). Beginning with the Spanish explorers of the sixteenth century, European contact and colonization had drastic effects on the cultures and islands of Oceania. Spain's success in establishing a trade route across the region led other European countries to explore more regions in the hope of finding new lands and expanding their presence. During the seventeenth and eighteenth centuries, Dutch, French, and British expeditions sailed throughout the region and made significant geographic and scientific discoveries.

Although the Spanish were successful in developing trade routes across the ocean, it was not until the late eighteenth century that extensive trade was established by other nations. At that time the British were focusing their efforts on the colonization of Australia, while American trading vessels from New England were crossing the Pacific and establishing links with China. These voyages allowed traders and colonial powers alike to compile information about available resources of potential commercial interest, and soon stories of sandalwood and significant numbers of seals and whales reached the USA and Britain. This news produced an explosion in the numbers of ships roving the waters of Oceania by the early nineteenth century. The need for freshwater, food, and firewood during these journeys ultimately led to contact with nearly every archipelago, and these interactions had a profound effect on local cultural groups.

From the mid-nineteenth to early twentieth centuries, American and European powers developed their colonial holdings in many areas of Oceania. Initially, they served as supply and transshipment outposts for passing vessels, but soon they realized that the climate and environment of the Pacific islands also allowed for the harvest of guano for use in fertilizers and coconuts for copra. The development of large-scale agricultural production of crops like sugarcane resulted in the construction of colonial government towns and significant maritime infrastructure to assist in navigation and shipping.

The Pacific Ocean was relatively quiet during World War I; Japan and the USA quickly took

control of all German colonies there. At the end of the war, Japanese occupation of nearly all former German territories in the Pacific was formally recognized through the Treaty of Versailles. Japan quickly established administrative centers in many parts of Oceania and increased maritime infrastructure development through the construction of lighthouses and channel markers, as well as port-related facilities. By the 1930s Japanese military infrastructure construction was also increased in preparation for war.

The December 7, 1941 attack by Japan on the US Naval Base at Pearl Harbor in Hawaii had profound effects on Oceania. Many of its island archipelagos became the scene of World War II's Pacific Theater. Prewar occupation of these islands allowed the Japanese military to heavily fortify their installations and establish extensive air bases. Such was the strength of these fortifications that some of the most intense and bloodiest battles of the war were fought on the islands of the Pacific and in the sea and air surrounding them. The results of these battles were devastating and left a permanent mark on the islands.

Archaeology in the Pacific is dominated by two main foci: prehistoric colonization of the islands and the activities of the post-1500 historic period. Due to the number of maritime archaeology projects that have been undertaken in the region and the variety of topics covered, a thematic approach to this discussion is appropriate. The context for each theme, which includes colonization, exploration, European trade, resource extraction, conflict, and warfare, is provided, and examples of archaeological investigations pertaining to each are discussed below.

Colonization

Debates about the post-Pleistocene colonization of the islands and the origin of the first voyagers are ongoing, as research provides new information. According to Ian Lilley (2006: 5), approximately 3,500 years ago seafaring, pottery-making farmers in the Bismarck Archipelago established the "Lapita phenomenon" and were the first people to occupy remote Oceania. The Lapita debate is a major focus for archaeological investigations of coastal sites through Oceania and has taken a central theme in literature relating to Pacific prehistoric archaeology over the past decades. Though these studies attempt to determine the earliest occupation of Oceania through the association of pottery types and other aspects of cultures, no definite remains of the watercraft used by the voyagers to make the long trips between the islands have been identified. The reason for this can be explained by considering the organic nature of such craft and the tropical marine environment of the region. Rough sea conditions quickly break up abandoned or wrecked wooden vessels, and the remaining structure is quickly consumed by tropical wood-boring organisms. As watercraft would have been constructed almost entirely of wood and plant products, this would leave very little evidence aside from stone anchors and any stone implements that were onboard.

Submerged archaeological sites relating to prehistoric occupation include evidence of early seafaring and marine resource extraction. Sites containing stone anchors and fishing implements have been recorded in several areas of Oceania since the 1960s. Examples of archaeological investigations of such sites include those conducted in Hawaii, French Polynesia, and the Federated States of Micronesia (FSM).

Shell fishhooks and scattered basalt artifacts such as stone fishing weights and anchors are abundant in some sites around the island of Oahu in Hawaii. In 1996 archaeologists and students from the University of Hawaii conducted investigations of a scattered collection of lithic artifacts, fish trap weights, and octopus lures directly off of Waikiki (Van Tilburg 2002: 251). The study resulted in the hypothesis that the high-density fishing-related artifacts are found on nearshore-raised reefs due to a greater density of marine life concentrated in the area (Pfeffer 1995; Van Tilburg 2002: 251).

Another significant prehistoric maritime archaeological site is located in Mo'orea, French Polynesia, near Tupaparau Pass in the Afareaitu lagoon. Numerous hewn and worked stone objects have been recorded there; objects identified include stone anchors, fishing weights, finished basalt tools (adzes), and a small number of

domestic objects. Although the function of the site is still unknown, it is significant due to the fact that hundreds of objects are located in one area (L'Hour 2010: 47).

Archaeological evidence of marine resource extraction is common in Oceania. One type of site associated with marine subsistence strategies are fish traps. Such sites are especially abundant in the FSM state of Yap, where local people see their use as a sustainable fishing practice. A comprehensive archaeological survey of fish weirs (locally known as *aech*) was conducted to assist in prioritizing restoration work and to encourage the revitalization of their use. Conducted in association with the *aech* owners, village chiefs, and the Yap Historic Preservation Office (HPO) staff, the survey resulted in the location of hundreds of *aech* and the archaeological recording of a large number of them (Jeffrey and Pitmag 2010; Jeffrey 2011).

European Exploration

Early sixteenth-century Spanish explorers seeking a trade route between Acapulco (Mexico) and Manila (Philippines) were the first known Europeans to enter the Pacific. Once a course was established for what would become known as the Manila Galleon trade, the Spanish established a provisioning entrepôt for their ships at Guam and soon claimed islands in the Carolines, Solomons, and Marquesas. Dutch traders, already long established in Southeast Asia, are also known to have explored parts of the South Pacific in the seventeenth and eighteenth centuries. However, it was not until the eighteenth and nineteenth centuries that French and English expeditions made significant geographic discoveries in the region. By the nineteenth century other nations also explored the Pacific while making circumnavigations of the globe in the name of science.

Several vessels associated with the various expeditions are historically known to have come to grief on the treacherous reefs and in the extreme depths of the Pacific Ocean. An example of a maritime archaeological investigation of lost ships of exploration is that of the French vessels *Astrolabe* and *Boussole* in the Solomon Islands. Explorer Jean-François de Galaup, comte de Lapérouse, was engaged in a scientific and exploratory expedition in the region when the two vessels were lost off the island of Vanikoro in the Santa Cruz group in 1788. Though the sites were first discovered by French explorers in the early nineteenth century, they were not archaeologically investigated until 1986. A multinational research team recorded the wreck sites and also located the remains of associated survivors' camps (Stanbury and Green 2004).

Shipwrecks are not the only archaeological remains of European exploration that have been identified. In many cases ships narrowly escaped wrecking but were forced to sever anchor cables in the process. Thanks to excellent record keeping by expedition leaders and their crews, the approximate locations of many lost anchors from such ships are known and, in some cases, have been archaeologically documented. Examples of these are anchors identified in Tahiti from the late eighteenth-century expeditions of both Captain James Cook of England and Louis Antoine de Bougainville of France (L'Hour 2010: 47–48).

European Trade

While archaeological evidence sheds light on the extensive prehistoric trade networks that existed between the islands, European trade also left identifiable physical impacts. Colonial ports were built throughout Oceania to assist with shipping cargos. Maritime archaeological sites associated with trade include shipwrecked trading vessels, and maritime infrastructure sites have been investigated in nearly every island group.

Of the sites associated with the post-1500 European period are those related to the Manila Galleon trade. Many vessels are known to have been lost over the trade's four-century history, and shipwreck sites could provide a great deal of information about the vessels involved, the cargos that they carried, and the conditions that existed onboard. And while the remains of several Manila Galleons have been located, so far all of them have been claimed and impacted by treasure-hunting companies looking to profit from them. Spanish shipwreck sites located near the main provisioning points of Guam, Rota, and Saipan

have been salvaged by treasure hunters, and as a result valuable archaeological data is lost forever.

Wrecks of merchant vessels propelled by sail, steam, and petroleum have been investigated in waters surrounding nearly every archipelago in Oceania. One example of a wreck associated with the copra trade is that of the hulk *Elsanore* located at the port of Levuka on the island of Ovalau, Fiji. *Elsanore* was loaded with a cargo of 500 t of copra when it was destroyed by fire in 1895. The wreck site was investigated by archaeologists from the Australian National Maritime Museum in 1998 (Hosty and Hundley 1998).

One unique example of a wrecked trading vessel is that of *Lenora*, a brig that belonged to the famous Pacific pirate Bully Hayes. Hayes' story was sensationalized by the popular media of the time which portrayed him to be a shrewd swindler, trader, blackbirder, and bigamist (Russell 1982: 4). Hayes used *Lenora* to engage in the illicit trade known as blackbirding, or kidnapping of islanders and using them as forced labor. In 1981 archaeologists with the US National Park Service (NPS), the Kosrae Historic Preservation Office, and the (then) Office of Historic Preservation, Trust Territory of the Pacific Islands investigated the remains of the wooden brig *Lenora* in Utwe Harbor, Kosrae (Carrell 1991).

Resource Extraction

The marine environment and close proximity to deep water of the islands of Oceania has allowed for the exploitation of both pelagic and shallow water species since initial colonization. And over the past 200 years, European and American interests developed industries related to resource extraction in the region. Such industrial activities include fishing, sealing, whaling, pearling, bêche-de-mer collecting, and guano mining. Archaeological investigations of the remains of the various methods associated with these industries have been carried out in several areas. Of these projects, perhaps the most comprehensive research has been conducted on the archaeology of whaling.

By the late eighteenth century, British and American whaleships rounded Cape Horn and entered the Pacific. There, they found rich, new hunting grounds which soon led increasing numbers of whalers who explored the region in search of their prey. In the nineteenth century, vessels equipped for voyages of several years in length roamed throughout Oceania until they filled their holds with valuable oil. Due to the harsh environmental conditions encountered, many vessels were lost on remote and uncharted reefs. Sites of wrecked whaling vessels have been identified in the waters surrounding the FSM states of Pohnpei and Kosrae, as well as Hawaii. Of the known sites of wrecked whaleships that have been investigated archaeologically, those located in Papahānaumokuākea Marine National Monument (in the northwestern Hawaiian Islands) present a unique opportunity to study contemporary vessels from competing nations and the technological changes that occurred over the industry's peak period. Of the ten British and American whaling vessels that are known to have wrecked within the boundaries of Papahānaumokuākea over the first half of the nineteenth century, five have been archaeologically recorded and are the subject of ongoing research (Raupp and Gleason 2010; Raupp 2015).

Conflict and Warfare

No other post-1500 European activity has added more to the archaeological record of Oceania than warfare. Activities such as prewar military infrastructure development, commerce raiding, weapons testing, and battles on land, in the air, and underwater have all greatly affected the Pacific region. The physical remains of these activities on land include fortified structures, command posts, gun emplacements, storage structures, and airstrips. In the waters surrounding the various island chains exist the remains of wrecked ships, landing craft, assault vehicles, and aircraft deposited either as a result of conflict or in its aftermath. Archaeological sites associated with the US Civil War, World War I, World War II, and post-World War II nuclear weapons testing have all been investigated in Oceania.

Of the warfare-related sites in Oceania, none are more prevalent than those associated with World War II. Clandestine prewar Japanese military buildup began in the 1930s in Oceania, and by the end of the decade, extensive, extremely

well-fortified bases and ports were complete. Japanese assaults in the region set the scene for some of the most intense combat of the war and left battlefields littered with detritus. While in some places lost or abandoned Allied and Axis military craft were often left to deteriorate in situ, in others they were relocated to dumping areas as part of cleanup efforts and the necessary clearance of obstructions to navigation. As a result of such activities, a large number of unique archaeological sites exist in both shallow and deepwater environments.

For many years when such sites were identified, they often only preliminarily surveyed as a result of proposed harbor developments or management planning activities. However, over the past few decades, the significance of these sites and their connection to a shared, global heritage has resulted in an increasing interest among both cultural heritage managers and academic researchers. In that time, archaeological investigations of World War II sites have been undertaken in most of the archipelagos of Oceania, as well as in deepwater locations throughout the Pacific. Beginning with inventories of known sites and surveys at battle locations, research has since flourished, and many innovative projects have been undertaken to better understand the physical and cultural processes that affect sites and in turn how their presence has affected the cultures and environments that surround them. Notable projects include the extensive documentation and interpretation of American vessels and planes sunk as a result of the Japanese attack on Pearl Harbor by the US National Park Service (Lenihan 1990; Rodgers et al. 1998); collaborative efforts by the University of Hawaii, NOAA, and NPS to investigate and develop a long-term management strategy for the remains of a Japanese midget submarine sunk in deep water off of Hawaii (Van Tilburg 2006, 2007); the use of anthropological approaches to understanding the range of values, meanings, and relevance that archaeological sites in Chuuk Lagoon have for different cultural groups and how this knowledge can assist in site management (Jeffrey 2007); and the development of an underwater heritage trail aimed at highlighting the many wrecks associated with the 1944 Battle of Saipan and encouraging site protection and preservation through sustainable, heritage tourism (McKinnon 2011; McKinnon and Carrell 2015).

Key Issues/Current Debates

Many of the key issues faced by maritime archaeological sites in the Pacific are the same as those in other parts of the world. However, issues related to site protection, permitting and access, preservation, and conservation are all compounded by the enormous area in which they exist. The vast distances that must be traversed to access sites make archaeological research and management in many parts of Oceania difficult. The costs associated with accessing these sites are a major limiting factor in the amount of time that can be spent surveying, recording, and/or monitoring them. As such it is possible for unscrupulous visitors and salvage operations to impact the archaeological context of sites without being detected. And as with archaeological sites in other parts of the world, perhaps the most important method for providing protection to archaeological sites in Oceania is through education.

Efforts to increase awareness of the fragile and irreplaceable nature of maritime archaeological sites in Oceania are underway and appear to be achieving success in many areas. An example of such can be seen in attitudes toward World War II shipwreck sites in Micronesia. For decades many of these sites were explored and negatively impacted for subsistence, commercial, and recreational purposes. A common practice the world over, local fishers take advantage of the unique artificial reef habitats created by submerged wrecks; however, the methods used for catching fish can be devastating to both archaeological sites and to the fishers themselves. These same wrecks have long been popular with diving tourists as well, and early diving activities often had detrimental effects on heritage sites through looting of artifacts and structural stress caused by improper anchoring practices. However, for the past 20 years, government agencies throughout the region have increasingly implemented fishing

and diving regulations and educated operators about the need to preserve and protect the integrity of sites. Over time these efforts have succeeded in transforming them into sustainable, heritage tourism ventures.

Future Directions

The large number of sites that exist in the coastal zones and waters of Oceania and the range of time represented by them provide seemingly endless options for maritime archaeology. Research into the many different phases of human interaction with the Pacific Ocean has long been established, and significant advances in knowledge are consistently being made into Indigenous cultural and environmental adaptation, as well as the activities of historic periods.

Future maritime archaeological research and management strategies in the region should employ cost-effective methods to achieve goals that are both culturally and environmentally sensitive. In order to do this, collaboration is the most important key. In times past, inclusion of the various cultural groups of many island communities has often been neglected by researchers, which has resulted in negative impacts upon them and often one-sided interpretations of results. However, recent approaches to archaeological research in the region have focused on inclusive practices and community consultation to ensure that all groups have a voice and local wisdom is respected. In terms of physical characteristics, the environments in which sites exist offer opportunities for collaboration with members of the community that use the sites and scientists from many different disciplines. Such collaboration will lead to a more holistic understanding of how sites have affected the environments in which they were deposited and, in turn, the effects of their presence on those same environments.

Though the vast distances separating Pacific archipelagos have been seen as a major limitation for researchers operating on often unreliable sources of funding, they can also be seen as invisible barriers that provide increased levels of protection to sites. While it is true that for many years sites have been visited, and often negatively impacted, by resourceful divers and relic hunters, the high costs of reaching many areas of Oceania have likely been deterrents to other more destructive commercial ventures like scrap metal operations and large-scale land and port development. As a result, many maritime archaeological sites in Oceania are well preserved and hold great potential to provide insight into human interaction with the world's largest ocean.

Paddayya, Katragadda

Praveena Gullapalli[1] and Richa Jhaldiyal[2]
[1]Rhode Island College, Providence, RI, USA
[2]Department of Anthropology, Ohio State University, Columbus, OH, USA

Basic Biographical Information

Katragadda Paddayya received his Ph.D. from Poona University (now University of Pune) in 1968, where he studied under Dr. H. D. Sankalia. Sankalia founded the Department of Archaeology at Deccan College Post-Graduate and Research Institute in Pune, India. Paddayya has held a series of positions at Deccan College including Lecturer in European Prehistory, Reader in Field Archaeology, Professor of Geoarchaeology, and Director of the institution. He is currently Professor Emeritus at Deccan College and is on the editorial advisory boards of the *Indian Historical Review* and the *Journal of Social Archaeology*. He is an honorary fellow of the Society of Antiquaries of London, and most recently, in 2012, he was awarded the Padma Shri by the Government of India (a national civilian award granted for exceptional and distinguished service).

Major Accomplishments

Paddayya's fieldwork has been underpinned and shaped by an exploration of archaeological epistemology, including significant engagement with processual archaeology (1990); as significant as his fieldwork have been his explicit discussions of the nature and development of archaeological theory in India (1995). His field research has focused on the archaeology of the Shorapur Doab in northern Karnataka, India, especially the Paleolithic

and Neolithic landscapes of the region. His work, spanning more than 30 years, has made this previously little-known region into one of the best documented through extensive systematic surveys and detailed excavations (Paddayya 1982, 2007a; Paddayya et al. 2000). This research, beginning with his dissertation fieldwork on the Neolithic and subsequent projects on the Paleolithic sites of the Hunsgi and Baichbal basins in the same region, has emphasized contextualizing sites within environmental and cultural landscapes (Paddayya 1982) and the role of formation processes in the creation of the archaeological record (Paddayya 2007b).

Paddayya has consistently argued that questions of chronology and the reconstruction of the paleoenvironment and past lifeways could be better understood through intensive regional surveys and with a landscape and settlement system perspective, marking a significant departure from the way of prehistoric research was being done in India. This shift in research orientation led to the discovery of many Acheulian sites in varied topographic and sedimentary contexts and allowed for a reconstruction of the Paleolithic cultural landscape. Such an approach has helped identify sites like Isampur, an Acheulian quarry site with evidence for various stages of manufacture. At this site he and his colleagues have delineated toolmaking processes and behaviors (Paddayya et al. 2000) and have explored the possibility of understanding hominid cognition (Shipton et al. 2009). He has similarly contextualized the Neolithic ashmounds of the region, arguing that the ashmounds had to be understood as a part of the physical and cultural landscape and in relation to the various contemporaneous settlements that surrounded them (Paddayya 2002).

Paddayya has sought to engage with global archaeological theory and explore its relevance to the Indian context. While acknowledging that archaeology was introduced to India by Europeans, he emphasizes the fact that Indian archaeologists need to grapple with its theoretical apparatus to make it truly productive in India. The uncritical acceptance of archaeological theory would be as problematic as the uncritical rejection of it – rather, there is a space for the development of an Indian archaeological epistemology. For example, in "Theoretical Perspectives in Indian Archaeology" (1995), Paddayya lays out what he calls "indigenous" traditions for studying and understanding the past, such as Hindu and Buddhist historical traditions, and argues that post-processual approaches to the Indian past are possible by being cognizant of the Indian epistemological and philosophical contexts. This engagement with the local context is also seen in his attempts to bring archaeology to the public, either through writing popular articles in English and other Indian languages or the establishment of a museum in the village of Hunsgi and encouraging local schools to visit his archaeological excavations.

Paddy Soils: Environmental Analyses

Heejin Lee
Division of Cultural Heritage Convergence, Korea University, Sejong City, South Korea

Introduction

Rice is a major staple crop in the world today. The rice-growing countries are most of Asian countries, parts of Africa, Europe, and America under tropical, subtropical, and temperate climates. Such significance has drawn enormous attention to the agricultural history of rice from an agronomic perspective. Its historical development has been suggested by excavation of ancient paddy fields and ethnoarchaeobotanical research on rice remains and ancient literature studies. However, paddy soil, a type of modified soil by wet rice farming, has been rarely researched regarding its paleoenvironmental conditions and cultivation modes. A limited number of prehistoric and historical paddy fields have been investigated: China, Japan, Korea, and Sri Lanka. Here, some general soil pedogenic processes in paddy soil associated with agricultural regimes and research topics on ancient paddy soils are briefly introduced.

Definition

A paddy field is an artificially submerged habitat of the rice plant created by either using naturally flooded low-lying land or by constructing a bounded field system to keep water with additional irrigation facilities. Human-controlled irrigation schemes were initially determined by local climates and landforms and advanced by technical development in water management over time. Geomorphological settings of paddy fields are generally classified into five types. They include flood-prone, rain-fed lowland, irrigated, rain-fed lowland, and upland. At the micro-topographic level, ground and surface water regimes in wetland paddy cultivation based on longevity of saturation encompass stagnant water, stagnogley, and pseudogley, which significantly affect soil physical alteration as well as cultivation modes. The most general types are irrigated stagnogley- and pseudogley-type paddy soil resulting from submergence and drainage, and their common characteristics observed from buried paddy fields are dark-colored soil with high organic content and precipitated nodules or stains of iron and manganese due to repeated oxidation and reduction processes (Moormann and Van Breemen 1978; Greenland 1997).

Key Issues

Compared to macroremains of rice, recognition of cultivar, and cultivation contexts, employing

genetic markers and morphological variations is relatively standardized for cross-regional comparison; ancient agricultural soils went through more complicated postdepositional processes and tend to be affected by sedimentation after abandonment of the field. Moreover, locally inherited soil properties such as parent material, acidity, and soil texture are highly varied, and their physical and chemical responses to cultivation activities are dynamic. Hence, manifestation of agricultural effects on soil physiochemical alternation is irregular, and choosing parameters to determine land use dynamics of paddy rice farming is problematic. However, despite the roles played by local properties in pedogenesis as well as effects by cultivation, there are a few common features of paddy soils to note.

Changes to the physical properties of soils by cultivation are induced by puddling (wet tillage) and plowing while preparing land turns and mixes, through breaking up of soil aggregates and restructuration. Consequently, it causes a plow pan formation by downward movement of clay, creating impermeable zones and constraining plowing effects within the A horizon. On a microscopic scale, concentration of fine particles such as clay and silt, and formation of anomalous clay pedofeatures, has been observed (Miura et al. 1992; He et al. 2008; Lee et al. 2014; Lee and French 2016). Concurrently, there are some changes in soil microstructure and pore space, depending on local soil composition by wetting/drying processes and puddling (Eickhorst and Tippköter 2009).

A peculiarity of rice paddy cultivation is considered to be its infield irrigation regime, which is comprised of artificial waterlogging and intermittent drainage (De Datta 1981). Frequent submergence and desaturation of the land geared at providing air to rice plant roots, as well as weeding, usually triggered complex redoximorphic features of iron and manganese (including precipitated nodules and formation of iron pan) as well as gleying of soil (which is caused by iron movement in waterlogged soil). As a result of the accumulation of organic matter and repressed anaerobic decomposition processes caused by waterlogging, paddy soil usually exhibits high organic components in various forms including fresh organic residue, DOM (dissolved organic matter), and macro- and micro-charcoals. DOM in paddy field is a major contributor of emitted atmospheric methane, which can be stored in ancient paddy soil (Pfeffer 1995; Kögel-Knabner et al. 2010). On the other hand, burning the field after harvest, as well as applications of fertilizers (such as fermented animal manure, crop residue, and/or modern chemical fertilizers), would result in changes to some soil components such as P and Si. In the case of paddy soil, however, use of conventional techniques to study archaeological cultivated soils, such as measurements of phosphate concentrations and magnetic susceptibility enhancement (the latter employed to detect burning), is problematic due to gleying, leaching, and the fact that relatively high values of phosphate and nitrogen can be attributed to fertilizer usage (Kögel-Knabner et al. 2010).

More intensive paddy rice cultivation is reported to trigger hydromorphic degradation by leaching of iron as well as clay domain alignment changes and chemical components of Si, Al from clay minerals, and various soluble elements, resulting in the formation of an E horizon under the paddy soil (Brinkman 1970; Kyuma 2004). Furthermore, redox processes in wetland likely cause precipitation of minerals such as pyrite and siderite. In arid climatic zone, salinization due to excessive water evaporation by high temperature on irrigated paddy soils generally occurs as a form of land deterioration.

Although a line of conventional agronomic research on physiochemical composition of paddy soil is informative, its resolution is not high enough to reflect such diversified cultivation mode changes in archaeological paddy soils. In addition to inherited environmental conditions, the main variables to determine the productivity of rice yields and reflection of past cultivation techniques are soil fertility, cultivar variety, planting density, weeding, irrigation regimes, and scheduling corresponding to growth of plant. Issues can be extended to recognizing duration of past agricultural land including discontinuance of land use often resulting in preservation of paddy field by abandonment and minor local environmental fluctuations in ancient times through soil analyses. Other associated topics such as

indigenous or lost methods to replenish soil fertility (Barnes 1990), assessing natural soil fertility by parent material and addition of nutrients by regular flooding, crop rotation patterns, multiple croppings per year, and long-term interplay with local environmental changes such as groundwater-level fluctuations and sea level changes (Zong et al. 2007) are rarely studied and expected to be addressed in further ancient paddy soil research.

The recent geochemical and soil micromorphological investigations on ancient paddy soils appear to be able to provide detailed information regarding the earliest forms of rice cultivation and various ancient wet rice farming schemes.

In geochemistry, increase of soil organic matter, movement of iron and manganese, and removal of calcium carbonate in calcareous soil affected by long-term cultivation are noted through examination of a paddy soil chronosequence spanning 1000 years (Chen et al. 2011). Some view the emergence of paddy rice cultivation as a more active form of rice plant use by inferring infield burning through increased micro-charcoal contents coupled with microfossil evidence at the Kuahuqiao site between 7700 and 7550 cal. year BP and at the Tianluoshan site during 5000–2500 BCE, southeast China (Zheng et al. 2006; Zong et al. 2007). In particular, slash-burn management mode as incipient irrigation cultivation system is suggested by fire scar observed in electronic scanning images from the soil sample of the Majiabang period layer at the Choudun site(~6500 year BP) (Hu et al. 2013). Recent investigation of the Huizui site in the Loess Plateau of northern China indicates that the Neolithic Yangshao culture layer dating ca. 6600 cal BP is likely to be the relic of plausibly paddy farming field with a sign of trampling and redoximorphic features as well as the possibility of manuring evidenced by high phosphate contents (Rosen et al. 2017). A series of cultivation activities and their associated pedofeatures such as trace of harvest by uprooting, presumed application of manuring, burning in field, and development of irrigation toward more human water controlling regimes during Liangzhu period (c. 7000–4000 BP) at the Maoshan site near the lower Yangtze region (Zhuang et al. 2014). Noticeably, it is plausible to detect difference between rain-fed and advanced artificial irrigation regimes from prehistoric (c. 1000 BCE) and early historical paddy soils (400–1000 CE) at the Gulhwa and Pyunggeo sites, South Korea, by silty clay concentration pedofeatures exhibiting hydrological alteration and degradation due to irrigation scheme changes (Lee et al. 2014).

However, the complex nature of paddy soil chemistry and pedogenesis requires to examine ancient agricultural soils in further detail due to the complex nature of paddy soil chemistry. Multiple qualitative analytical techniques can be expected to yield more solid results in detecting the evolution of paddy rice farming and its locally diversified trajectories. In particular, geoarchaeological survey allied with archaeoethnobotanical research and archaeological excavation of buried ancient field systems and irrigation facilities is known to be informative.

It is required to building up a dataset of chemical and physical soil alterations associated with agricultural practices based on samples from multiple ancient buried paddy soils. This would serve as a crucial tool to assess early paddy soils in which clear field system features are not usually preserved well to understand paleoenvironmental conditions and cultivation modes. Further research is also needed to identify possible signatures of different paddy cultivation regimes and to shed light on degradation due to excessive land use. Another challenge is to detect the start of dry rice farming (upland rice) and to recognize paleosols under the influence of dry rice farming.

[2]Abdul Wali Khan University Museum, Mardan, Pakistan

Introduction

A museum is a nonprofitable institution that caters for conservation and exhibition of artifacts of significant value and educates the society about the human past and her environment through material evidence. The objects in a museum relating to ancient cultures and civilizations are organized in such a manner that spectators can conceive the exact picture of the past. The archaeological investigations in Pakistan reveal the earliest human occupation of Soan Valley near Rawalpindi and Sanghao Cave in Mardan since times prehistoric. The prehistoric caves, rockshelters, workshops, and quarries reported in the tribal belt, Mohmand and Bajaur agencies, Rohri Hills, and the Thar Desert further testify the existence of prehistoric occupations in Pakistan. The evidence of the Neolithic Culture Phase dating from the 9th to the 4th millennium BCE comes from the sites of Mehrgarh, Gumla, Jhandi Babar-I, and Sheri Khan Tarakai. The excavations at Kot Diji and Rehman Dheri provide substantial proof of this period in Sindh and

Khyber Pakhtunkhwa, respectively, followed by an urbanized and developed Indus Valley or Harappan Civilization, which was almost contemporary to the Egyptian and Mesopotamian Civilizations, followed by the Gandhara grave culture or protohistoric cemetery sites dating to the 2nd millennium BCE were discovered in Swat, Dir, Malakand, Bajaur-Mohmand, Chitral, Peshawar, and Taxila regions. The Gandhara Civilization existed in this region from sixth century BCE to fifth century CE. The White Huns, Hindu Shahis, Ghaznavids, Mughals, Durranis, Sikhs, and British ruled and left their footprints in this part of the world from sixth to twentieth century CE. Most of the major museums of the world have relics of the Indus Valley and Gandhara Civilizations exhibited therein. The concept of this entry is to highlight the history of archaeological museums in Pakistan from the 1850s to 2012. This report will serve as a documentary proof of the latest development of museums in Pakistan and will make the world aware of the scope of materials available and exhibited in the Pakistani museums.

Key Issues

The development of museums over the land where today Pakistan exists started soon after the establishment of the British Government. The first museum was established in Karachi in 1851, followed by one each in Lahore in 1864, Quetta in 1900, and Peshawar in 1907. All of these were public museums and represented mostly ethnological collections. Besides, a few museums were also constructed in some institutions of Lyallpur (present Faisalabad) in 1909 and Lahore in 1910 (Natural History Museum in Government College) and zoological museums, one each at Islamia College, Peshawar, and Rawalpindi both in 1934 for education and research purposes. As a result of large-scale explorations and excavations, a number of site museums were established at Taxila in 1918, Mohenjo-daro in 1925, and Harappa in 1926. In 1937, a private museum was established at Lahore with the title of "Faqir Khana" (Dar 1981: 13). The Swat Museum in 1959 was founded by the Wali of Swat and Dir Museum in 1969 by the then Governor of the province. A noticeable development in the establishment of museums was observed; six archaeological museums were added to the list in Pakistan during 2002–2006 by the Provincial Directorate of Archaeology and Museums, Government of Khyber Pakhtunkhwa, under the directorship of Prof. Ihsan Ali. Later on, three more museums, two by Hazara University, Mansehra, in 2007–2008 and one by Abdul Wali Khan University, Mardan, in 2012, were established by Prof. Ihsan Ali during his tenures as Vice Chancellor. These museums are located in Gor Khuttree, Peshawar; Pushkalavati Charsadda; Mardan district; Hund, Swabi; Chitral district; Bannu district; Abbottabad district; Hazara University, Mansehra; and Abdul Wali Khan University Mardan. All these museums are functional and represent archaeological and cultural profile of the respective regions of the country.

The Victoria Museum, Karachi

This Victoria Museum (see Fig. 1) was established by Sir Bartle Frere in 1851 in Karachi (Morley 1981: 10). Originally the museum housed objects of both archaeological and ethnological nature and was representing the artistry, archaeology, and natural history of the country. The museum building was later used by the Karachi Municipal Corporation Department in 1870. Likewise in 1908, various alterations and constructions within and the surroundings of Burns Gardens completely lost the originality of this museum in terms of its architecture and use. So due to lack of interest and awareness about the role of museums in societies, this museum remained abandoned since 1870, and the fate of the materials is not known as there is no such record of it.

The Lahore Museum, Lahore

The Lahore Museum (see Fig. 2) previously known as Jubilee Museum, Central Museum, and Punjab Museum was established by the British Government in 1849. This museum was first opened in Wazir Khan Baradari and represented

Pakistan: Archaeological Museums, Fig. 1 The Victoria Museum, Karachi

Pakistan: Archaeological Museums, Fig. 2 The Lahore Museum, Lahore

both archaeological and ethnological cultures of the region. Their antiquities immensely suffered in 1947, when major pieces were shifted to India under an agreement of devolution of cultural properties. Later on the museum building was occupied by the Punjab Public Library. The present Lahore Museum is located near old Food Street in Lahore district, housing rich collection of Buddhist and Islamic art pieces. The fasting Buddha is one among its unique collections. The contributions in the form of explorations, excavations, surveys, and documentations of the Archaeology Department and NCA Department of Punjab University produced valuable antiquities,

which are displayed in the museum representing a complete profile of the regions.

The McMahon Museum, Quetta

The developmental process of this museum was started in 1900 and the museum was formally opened to the public in 1906. Originally the museum housed antiquities of natural history, arts, crafts, and archaeological interest that represented the culture, ethnicity, lifestyle, and traditions of Baluchistan, Afghanistan, Persia, and Arabia. These antiquities were jointly collected by Mr. Hughes Butter and Sir Aurel Stein. In 1935, as a result of a devastating earthquake, most the museum building was damaged. Since then, the museum was shut down and the antiquities were dumped in municipal warehouses. Today, nobody knows anything about the precious antiquities that the museum displayed.

The Taxila Museum

Sir Alexander Cunningham first started archaeological investigations in Taxila during the period 1913–1934 and produced rich material of sculptures, jewelry, and household utensils. Initially these materials were displayed in a temporary hall which was then shifted to the museum. In 1918, the foundation stone of a new building was laid by the then Viceroy of India Lord Chelmsford and it was formally inaugurated as a museum in 1928 (Ashraf and Lone 2005: 41). Currently the museum is located at about 5 km off the main Peshawar-Islamabad G. T. Road, at a distance of 35 km from Islamabad, with a rich collection of Gandharan art, principally coming from the sites of Bhir Mound, Sirkap, Sirsukh, and the Buddhist monasteries and stupas of Dharmarajika, Julian, and Mohra Muradu (see Fig. 3).

The Peshawar Museum, Peshawar

The Peshawar Museum (see Fig. 4) was built in 1906 in the memory of Queen Victoria and formally opened in November 1907. In its early days the Peshawar Municipality ran the Peshawar Museum. In 1917 the building and museum was transferred to Local Government supervision. The superintendent of the Archaeological Survey of India, Frontier Circle, acted as curator of the museum. In 1927, the Frontier Circle Office was shifted to Lahore. A full-time curator was appointed for the Peshawar Museum, and the building along with antiquities was transferred to the Provincial Government.

Often the main hall of the Peshawar museum building was used for investitures, balls, departmental examinations, tea parties, and sessions of the Legislative Council. The museum collections were displayed in the vestibule, side galleries, and upper galleries of the building. The exhibition area covered 4,850 sq. ft. The first session of the Legislative Assembly of Khyber Pakhtunkhwa, the then North-West Frontier Province, was first

Pakistan: Archaeological Museums, Fig. 3 The Taxila Museum

Pakistan: Archaeological Museums, Fig. 4 The Peshawar Museum, Peshawar

time held here on April 19, 1932, inaugurated by the Viceroy of India, Lord Willington (Khan 1972: 3). The Provincial Government fully realized the difficulty and inconvenience caused to visitors to the museum and disallowed the use of the hall for political purposes. After independence, the museum remained under the direct control of the Director of Public Instructions, Government of Khyber Pakhtunkhwa, the then NWFP. In 1971, an autonomous body, under a Board of Governors, headed by the Chief Secretary, was instituted to run the affairs of the museum. In 1992, the Government of Khyber Pakhtunkhwa, the then NWFP, established a Directorate of Archaeology and Museums to ensure better protection, preservation, promotion, and safeguarding of the archaeological and cultural heritage of the province; thus the Peshawar Museum became part of the Provincial Directorate.

The original two-story building, an amalgamation of British and Mughal style architecture, consisted of a main hall and two side aisles on the ground and first floor, surmounted by four elegant cupolas and small pinnacles on all corners. In 1969–1970 on the eastern and western sides of the building, two halls were added in a similar fashion. In 1974–1975, a second story was added to these two side halls. A new block under a project "Extension of Peshawar Museum" was approved in the year 2002 under the supervision of the principal author of this chapter at a cost of Rs. 33.11 million. The project had two components: first, an extension of the museum to construct an Islamic Block with two galleries, a conservation laboratory, two halls for the reserve collection, offices of the Provincial Directorate, and a cafeteria. The second component was a complete remodeling of the existing building including replacement of showcases, lighting, labeling, and display works in all galleries of the existing main building along with refurbishing the floor, ceiling, and structures. When the project was completed, the antiquities were displayed according to international standards.

The museum since its early days housed a rich collection of the Gandhara art pieces, excavated and recovered from the major Gandharan sites like Shah-Ji-Ki-Dheri in Peshawar district; Sahri Bahlol, Jamal Garhi, Shahbaz Garhi, and Takht-i-Bahi in Mardan district; and Aziz Dehri in Swabi and from other Gandharan sites excavated by both British and Pakistani scholars. The main collection includes Gandharan sculptures, coins, manuscripts, and copies of the Holy Qurans, inscriptions, weapons, dresses, jewelry, Kalash effigies, Mughals and later-period paintings, household objects, and local and Persian handicrafts. Today the Peshawar Museum is best known for its collection and is ranked as the largest museum in the world in terms of Buddhist art collections.

The Dir Museum, Chakdara

Dir district in terms of historical and cultural values is one of the most important regions among the districts of Khyber Pakhtunkhwa. Its territories stretched out between 34° 22′ and 35° 50′ north and 71° 02′ and 72° 30′ east and mainly comprised of the terrain drained by the Panjkora River and its tributaries. Dir takes its name from the name of a village, Dir, which served as a capital of the state during the Nawab regimes. It is surrounded by Swat district on the east, Bajaur on the west, Chitral on the north, and Malakand Agency on the south (see map). The archaeological expeditions in Dir district were started by the Department of Archaeology, University of Peshawar, during 1966–1969 and excavated sites like Andan Dheri, Chat Pat, Amluk Darra, Damkot, Balambat, Timargarha, Shah Dheri, Gumbatuna, and Shalkandi. To house the collection from these sites, the State Government of Dir constructed a museum in Chakdara. Capt. Rahatullah Khan Jaral, the then Political Agent of Dir Agency, proposed the Dir Museum and allocated a sum of Rs. 2,50,000 for its construction. The Provincial Government afterward allocated an additional fund of Rs. 4,90,000 for the construction of residential quarters, boundary wall, guest house, storage, and other facilities.

The museum building was designed by Mr. Saidal Khan, Consultant Architect of the Public Works Department (PWD) of Khyber Pakhtunkhwa, the then NWFP. The architect adopted the local style of architecture and constructed the museum with bare stone, called as Malakandi stone. The museum has a fort-like appearance, with a grand facade, consisting of an arched entrance, two square-corner picket towers, and battlements on the parapet (see Fig. 5).

The museum remained as a state museum until 1969, and when the state was merged into the province, the museum was handed over to the Provincial Government. The Provincial Government constituted a Board of Governors under the Provincial Educational and Training Ordinance 1970 to run the affairs of the museum and was formally inaugurated on May 30, 1979, by Lt. General (Rtd.) Fazl-e-Haq, the then Governor of the province (Dar 1981: 17). However, the museum was properly organized in 1979. The purpose of the museum is to exhibit the extensive archaeological, Islamic, and ethnological materials of the area. The materials include Gandharan sculptures, coins, jewelry, and weapons.

Today the museum has a total collection of 2,161 objects, mainly Gandharan sculptures, coins, and ethnological materials. The display of the Gandharan objects, more than 1,444 in

Pakistan: Archaeological Museums, Fig. 5 The Dir Museum, Chakdara

number, revolves around the themes of Buddha's pre-birth and life stories, miracles, worship of symbols, relic caskets, and individual standing Buddha sculptures. The most represented of the pre-birth stories or Jatakas are Dipankara, Maitryakanyaka, Amara, Syama, and Vessantara Jatakas. The most represented scenes from the Buddha's life story include Queen Maya's dream, interpretation of the dream, birth of Siddhartha, bath scene, seven steps, going to school, writing lessons, wrestling matches, palace life, marriage scene, renunciation, great departure, ascetic life, first meditation, demon attacks, attaining enlightenment, first sermon at Sarnath, conversion of Ksyapa, monks, death scene, cremation of Buddha, distribution and guarding of relics, and the construction of stupas on the relics. The miracle of Sravasti and taming of a wild elephant are the two commonly represented miracles, along with different types of the relic caskets and stupa models, along with life-size Buddha statues. Other Gandharan representation comprises of boddhisattvas, atlantes, ichthyocentaurs, cupids, garland bearers, Corinthian, Persipoliton, Indo-Persipoliton pilasters, and decorative architectural fragments. Most of the Gandhara art pieces come from the sites of Andan Dheri, Chat Pat, Baghrajai, Bumbolai, Jabagai, Shalizar, Ramora, Tri Banda, Macho, Amluk Darra, Nasafa, Damkot, Bajaur and Talash, Dir, Malakand, Balambat, Timargarha, Shamlai Graves, Inayat Qila, Shah Dheri Damkot, Gumbatuna, Jandol, Matkani, and Shalkandi.

The Ethnological Gallery of the museum was established in 1977, reflecting on the cultural heritage of the area and presenting a general picture of the life of the people to the visitors. The ethnological material, 498 pieces in all, includes manuscripts, weapons, jewelry, dresses, ceramics, musical instruments, household objects, furniture, and wooden architectural elements.

The City Museum, Gor Khuttree, Peshawar

The City Museum (see Fig. 6) is located in the Gor Khuttree Complex and can be approached either through Chowk Yadgar from the west or Lahori Gate from northeast of the walled city of Peshawar. The complex occupies the highest point center of the city. This site has been identified with the place of Buddhist embellishment relating to "the tower of Buddha's bowl" and with Kanishka Vihara (Dani 1995). Mughal kings like Babur (Beveridge 1975), Akbar, and Jahangir talked about this site in their diaries and referred this site to the settlement and religious place of Hindu Jogis (a place where

Pakistan: Archaeological Museums, Fig. 6 The City Museum, Gor Khuttree, Peshawar

Hindu funeral sacrifices and Sardha ceremonies were held) (Raverty 1852: 22–23; Jaffer 1945: 203–204). It was Jahanara Begum, the daughter of Mughal King Shah Jahan (1050 HA or 1540 CE), who converted this site into a caravanserai and named it as Sara-e-Jehanabad and built a Jamia Masjid (a place where Friday prayers are held) and a Hamam (Jaffer 103–6). Upon the recommendation of Nur Jahan Begum, wife of another Mughal king Jahangir, a network of cells on four sides with lofty turrets at each corner, two high archway gates on the eastern and western sides, and two wells were constructed which covered a total of 700 sq. ft. area and completed the shape of a caravanserai (Ali et al. 2005: 228). Later on from 1838, the Italian General Paolo de Avitabile as Governor/Representative of the Sikh Government made major alterations in the complex. He converted the Jamia Masjid into Gorakhnath Temple and used the cells for official purposes (Jaffer 1945: 103; Durrani et al. 1997: 189). The addition of second storey structure upon the western gate was the alteration he made for public petition and official use (Jaffer 1945: 103). This site remained the focal point of the British Government as well. The 1912 fire brigade building and barracks on the eastern and southeastern corners, respectively, are the alternations they made. Currently, the site is under direct supervision of the Directorate of Archaeology and Museums and Crises Management Unit, Government of Khyber Pakhtunkhwa.

The City Museum was inaugurated on Pakistan Day on March 23, 2006, by the former Chief Minister Mr. Akram Khan Durrani under the leadership of the principal author of this chapter. The archaeological gallery of this museum represents a continuous profile of the Peshawar Valley in the form of excavation material recovered from the site of Gor Khuttree. This excavation was started by Prof. Dr. Ihsan Ali, the then Director of the Directorate of Archaeology and Museums, in 2002 and today the excavation area with a 49-m-deep trench claims the honor of the deepest excavation in the world, testified through the journal *Current World Archaeology* (Selkrik 2006: 20). The second gallery is of ethological culture of Peshawar, where household objects, traditional dresses, armaments, ornaments, musical instruments, arts, and craft objects are displayed. It is worth mentioning that the structural integrity of surviving monuments, museum antiquities, and excavation area within Gor Khuttree Complex produced M. Phil. and Ph. D. scholars at both national and international levels. Dr. Jennifer Campbell from Toronto University, Canada, and Dr. Shah Nazar and Mr. Fazal Sher from Peshawar University are a few scholars whose research was directly based upon the site.

The Pushkalavati Museum, Charsadda

The establishment of this museum (see Fig. 7) is closely linked with the historical background of the region. Pushkalavati, the modern Charsadda district being the first capital of Gandhara, is situated about 30 km to the northeast of Peshawar. The term Pushkalavati is a combination of two Prakrit words *Pushkara*/*Pushkala* and *wati*/*vati*, which, respectively, mean "lotus" and "city." The area is very fertile and has ponds full of lotus flowers. The lotus flower, which also symbolized Buddha in archaic sect, is still grown in Charsadda. The legendary Hariti Devi and Panchika were born here and converted to Buddhism by Lord Buddha. The Siyama Jataka also took place here (Sehrai 1982; Ali 2003). This region is also known as "Hashtnagar" which is a Persian word meaning "eight villages." According to Prof. Dani, this name is the corrupt form of "Astes Nagar," (city or village of Astes) after its ruler Astes who ruled over Gandhara before the onslaught of Alexander the Great (Dani 1966).

Here the remains of the two cities have been exposed at Bala Hisar and Shaikhan Dheri, opposite to each other. The second one is situated on the bank of river Jinde, a stream with its source in Malakand Agency flowing through Charsadda and joining the river Swat. The site of Bala Hisar yielded the material dated to the time of the Achaemenian, Greeks, Scytho-Parthians, and Kushans (Wheeler 1962). Prof. Ihsan Ali's survey conducted in 1993 discovered 144 sites of different types (Ali 1994). The report brought to light a good number of Buddhist stupas and monasteries in this region.

Pakistan: Archaeological Museums, Fig. 7 The Pushkalavati Museum, Charsadda

Keeping in view the historical wealth of the region, Prof. Ihsan Ali, former Director of the Directorate of Archaeology and Museum, initiated a project for the establishment of a museum on the site of Ghani Dheri, aiming to house both archaeological and ethnological material of the area and educate the people about their rich cultural properties. The museum building was completed, but due to departmental issues, this museum is yet to be opened for public.

The Mardan Museum, Mardan

The Mardan Museum (see Fig. 8) was proposed by Sahibzada Riaz Noor, the then Commissioner of Mardan, on December 29, 1990. He constituted a Board of Governors in January 1991 to help the establishment of the museum in Mardan district. The museum started functioning in March 1991, and the display work in the solitary hall, measuring 50 × 22 ft., was completed in April 1991. The Peshawar Museum donated 22 showcases for the display, while the Department of Archaeology, University of Peshawar, rendered technical support. In 1992, with the establishment of the Directorate of Archaeology and Museums, Government of Khyber Pakhtunkhwa, then NWFP, the Mardan Museum came under its administration. The Peshawar Museum provided 137 confiscated antiquities to start display work. Initially the old building of the Mardan Museum had a total collection of 419 artifacts, including 258 Gandharan sculptures; 127 coins of Kushan, later Kushan, Kushano-Sasanian, and Hindu Shahi dynasties; 6 terracotta animal figurines; 5 mercury containers; 10 household objects; and 13 agricultural tools. The subject matter of the Gandharan sculptures in the Mardan Museum of schist stone are Queen Maya's dream; birth of Siddhartha; bathing scene; the great departure; the first sermon at Sarnath; the conversion of Kśyapa; offerings to Buddha; distribution of the relics; worship of the wheel of law; stupa and alm bowl; Buddha with worshippers and monks; Buddha seated in reassurance pose (Abhaya Mudra); garland bearers; Buddha seated under arches in meditation pose (Dhayana Mudra); Corinthian, Persepolitan, and Aśokan capital; broken architectural elements of pillars, pilasters, harmika, dome, yashthi, chitras or umbrellas, spacers, and floral and geometrical decorative elements from votive and large stupas; broken pedestals with Buddha and Bodhisattva feet; broken hands in different postures; figures of sheep, lion, horse, peacock, and ichthyo-centaurs; and a seated figure of Ardoksho. The stucco sculptures include a seated Buddha in meditation pose (Dhyana Mudra), heads of Buddha, Bodhisattva, and common folk.

Though the initial collection of the Mardan Museum is based on the confiscated materials, later the excavated antiquities from Safiabad, Mardan, and Hund, Swabi, were also displayed in

Pakistan: Archaeological Museums, Fig. 8 The Mardan Museum, Mardan

the museum. Confiscated antiquities from Katlang, Rustam, and Baja police stations along with the donated objects were also displayed in the old building of the museum. From 2002 onward, under the leadership of Prof. Ihsan Ali, the then Director initiated a project for the establishment of a big museum because the old building's capacity was not enough to house the objects systematically. So the current Mardan Museum, which is located on Mardan-Charsadda road, was inaugurated by the Chief Minister Amir Haider Khan Hoti in 2008. The material displayed in the old building have been shifted here and displayed along with borrowed antiquities from the Peshawar Museum. Today this museum mainly represents the Buddhist art and architectural elements and educates the nation about the past glory of the region.

The Hund Museum, Swabi

The Hund Museum (see Fig. 9) was established upon the landscape which has been mentioned hundreds of years ago by various scholars, the earliest account of which came from Sarada inscription found at Hund which describes this region as Udabhandapura, meaning "the upper town" or high-altitude landscape (Rahman 1979a). Xuanzang, the Chinese pilgrim, who is also known as Hiuen Tsang in historical accounts, mentioned this site in his autobiography of 644 CE as Wa-to-kia-han-cha. Waihand and Ohanad are also the names used for the present site of Hund (Shakur 1946; Rahman 1979b; Ali 1999; Ali et al. 2005). Keeping in view the historical value of the site, the Directorate of Archaeology and Museums under the leadership of Prof. Dr. Ihsan Ali initiated a project based on various activities. In its first phase, the building for the museum, rest house, cafeteria, and a monumental Corinthian pillar in the memories of Alexander the Great has been completed, while in the second phase systematic excavations, aiming to determine the complete cultural profile of the region, and construction of a bypass road are yet to be completed. The current museum was inaugurated in 2009 by Mr. Sayed Aqil Shah, Sport, Youth Affairs, Tourism, Archaeology and Museum and represents both archaeological and ethnological wealth of the region.

The Bannu Museum, Bannu

Bannu basin is connected to the Gomal Valley and is surrounded by hills and mountains. It is very strategically located between the Balochistan plateau, Central Asia, and the plains of the greater Indus Valley. The area was inhabited in prehistoric

Pakistan: Archaeological Museums, Fig. 9 The Hund Museum, Swabi

times and it is no wonder that a few Neolithic settlements and prehistoric sites were recorded here. The sites of Sheri Khan Tarakai (Khan et al. 1986), Lewan, and Akra were excavated jointly by the University of Peshawar and the Bannu Archaeological Mission including the British Museum, the University of Cambridge, the University College London, and Bryn Mawr College from 1984 to 2001. Bannu, having rich cultural history in the form of material evidence, the Directorate of Archaeology and Museums has established a Museum of Archaeology and Ethnology near Allah Chowk, next to the Agriculture Office at Bannu, inaugurated by Mr. Sayed Aqil Shah, Minister for Sports, Tourism, Archaeology, and Youth Affairs, in 2011 (see Fig. 10).

The Chitral Museum, Chitral

Chitral district is one of the famous regions among the regions of Khyber Pakhtunkhwa and best known for its indigenous culture and quaint beauty. The district lies in the northwestern part of the province, between 71° 12′ and 73° 53′ longitude and between 35° 13′ and 36° 55′ latitude, bounded on the west by the Badakhshan Province of Afghanistan, on the east by the Northern Areas of Pakistan, on the north by the Wakhan Province of Afghanistan, and on the south by Dir and Swat districts (Ali et al. 2002). The altitude of the district from sea level is about 1,129 m at Arandu to 3,658 m at Baroghil (Raza 1994). The landscape is rugged and mountainous, while the

Pakistan: Archaeological Museums, Fig. 10 The Bannu Museum, Bannu

Pakistan: Archaeological Museums, Fig. 11 The Chitral Museum, Chitral

valleys developed in deep narrow and tortuous areas. Natural streams and channels of river Chitral run through all valleys (Dichter 1967). The archaeological expedition to Chitral conducted by Peshawar University; Bradford and Leicester Universities, UK; and the Directorate of Archaeology and Museums, Pakistan, unearthed a number of Gandhara grave culture or protohistoric cemetery sites in the district. The historic-period sites of this district have also contributed to the establishment of cultural profile of the district. Chitral, with its multifaceted culture, history, and archaeology, led the Directorate of Archaeology and Museums under the leadership of Prof. Dr. Ihsan Ali to establish a museum there. This museum was inaugurated by the late Saleh Mohammad, former Director, in 2008. The displayed material include dresses, armaments, ornaments, wooden effigies, household objects, and Gandhara grave culture materials (see Fig. 11).

Pakistan: Archaeological Museums, Fig. 12 The Abbott Museum, Abbottabad

The Abbott Museum, Abbottabad

Prof. Dr. Ihsan Ali as a Vice Chancellor of Hazara University, Mansehra, completed the establishment of this museum which was formally inaugurated by Mr. Nisar Muhammad Khan, the then Federal Minister, on February 22, 2008. The museum represents archaeological profile of the province in general and Abbottabad and Haripur districts in particular. In 2006–2007 the staff of the said museum under the leadership of Prof. Dr. Ihsan Ali initiated archaeological investigations in Hazara division. The surface collection of the survey conducted at Abbottabad and Haripur districts in the form of potsherds, bones, iron and metal objects, and photographs embellished the archaeological gallery of this museum. The material recovered from the pre-Buddhist grave site at Gankorineotek in Chitral district, excavated in 2008 through INSPIRE project, which was jointly run by Hazara University, Mansehra; Abdul Wali Khan University Mardan; British Council, Islamabad; and Leicester University, UK, are displayed in the main hall of this museum which educate the spectator about past glories (Ali et al. 2010). Household objects, armaments, ornaments, wooden furniture, and dresses are the main objects representing the culture and tradition of the area. The representation of Buddha's life story in watercolor painting and images of those political personalities who contributed directly or indirectly into the establishment of Abbottabad town in Burning Artwork in the said museum is the unique idea of Prof. Dr. Ihsan Ali to promote modernized arts and to pave a new way for students of other academia to contribute to archaeology. A beautiful cultural diorama adorned with traditional furniture, household utensils, and colorful arched facade is an eye-catching element of this museum (see Fig. 12).

Hazara University Museum, Mansehra

The establishment of the Hazara University Museum (see Fig. 13) is another achievement of Prof. Dr. Ihsan Ali as a Vice Chancellor. This museum was formally inaugurated by the then Honorable Governor of Khyber Pakhtunkhwa Mr. Owais Ahmad Ghani on February 13, 2008. It houses a diverse collection of archaeological and ethnological materials representing different occupational and cultural background of the region. The materials are either obtained through explorations and excavations or purchase and donation. The excavations at Gandhara grave

Pakistan: Archaeological Museums, Fig. 13 The Hazara University Museum, Mansehra

culture sites in Chitral district (Ibid) and Bedadi site in Shinkiari, Mansehra, revealed a fairly large number of antiquities which are displayed in the museum and give an authentic dataset for educational and research purposes. The material came from the archaeological survey of Mansehra district, conducted by the staff and students of the Archaeology Department under the leadership of Prof. Dr. Ihsan Ali in the form of potsherds, wooden objects, grave headstones, urn burials, and Gandharan stone panels that make up the collection of this museum. The museum also received a lavish donation of 114 relics and 72 coins from the Governor House. Household objects, ornaments, armaments, and Buddha birth scene in watercolor painting and different poses of Buddha in mirror work are of great interest for the spectators.

Museum of Archaeology and Ethnology, Abdul Wali Khan University Mardan

The Museum of Archaeology and Ethnology, Abdul Wali Khan University Mardan (see Fig. 14), is located at the main campus of the university, situated to the north of the Kabul River between 34° 05′ and 34° 32′ north and 71° 49′ and 72° 24′ east in the heart of ancient Gandhara about 64 km from Peshawar. The excavations at Sanghao Cave in Mardan district by Dr. A. H. Dani in 1963 pushed the history of this region back to 40,000 years (Dani 1999). King Asoka (third century BCE) inscribed the creed of Buddhism on the rocks at Shahbaz Garhi in Mardan and popularized the religion of peace and tranquility. During the time of Scytho-Parthians (first century BCE) and Kushanas (first century CE), the real expansion of Buddhism took place and a new era was ushered in. Hundreds of stupas and monasteries were erected for the propagation of the law of Dhamma. Chinese and Korean travelers and pilgrims, who came here, recorded the existence of these sites.

The site of Jamal Garhi, Sahri Bahlol and Shahbaz Garhi including Takht-i-Bahi which is on UNESCO's World Heritage List is located in this district that yielded a great volume of the Gandharan art pieces that are currently on display at Peshawar, Mardan, Lahore, and Karachi museums. Keeping in view the historical and cultural wealth of the area, Prof. Dr. Ihsan Ali, as a Vice Chancellor of the Abdul Wali Khan University Mardan, laid the foundation stone of the

Pakistan: Archaeological Museums, Fig. 14 A 3D view of the proposed Museum of Archaeology and Ethnology at Abdul Wali Khan University Mardan

University Museum of Archaeology and Ethnology on July 20, 2011, and formally inaugurated the museum through Sayed Aqil Shah, Minister for Sports, Tourism, Archaeology, and Museums and Youth Affairs on December 22, 2012. This museum has been established with the main objective to educate and engage staff and students in extramural activities of the university. The students are given an opportunity to improve and demonstrate their knowledge and communication, leadership, and management skills by designating them tasks related to different activities of the museum. This will enable them to improve their level of understanding about past and present glories. Moreover, it will not only change their environment but they can express their aptitude which will certainly help them choose a profession of their interest in the future. The museum is equipped with ethnological materials which are systematically displayed in eight galleries. The first two galleries represent household objects, ornaments, armaments, coins of different periods, and straw-made items mostly purchased and a few donated. The third gallery is a Swat cultural, where a diorama of Swat valley has been established, embellished with wooden art pieces like engraved pillars, doors, and furnitures. The fourth gallery represents Kalash culture, where the Gandhara grave culture objects, traditional Kalash household utensils, dresses, ornaments, and armaments have been displayed. The fifth gallery represents contemporary art gallery, where pieces of wooden, marble, and straw artwork present the artistry of the region. The sixth gallery presents the color of the province in the form of photographic representation, capturing the culture, traditional games, cuisines, built heritage, and beauty of the province. The seventh gallery represents the vision of Islamic art. Calligraphic Qurans, books, objects of wooden block printings, tile work, and decorative household objects are displayed here. The eighth gallery represents traditional dresses and jewelry. The last two galleries are kept vacant for the archaeological material, and it is hoped that archaeological material will soon be arranged via departmental loan act or donation or through excavations. The digitization of the museum artifacts has also been started, and each object is recorded on a database after its physical verification. The detailed description of selected objects like jewelry, Islamic calligraphy, wood art, marble art, and henna art, from barter system to coinage and

Introduction

Large and imposing prehistoric stone monuments never appear to stand in isolation nor are they constructed as a single event. Since the advent of chronometric dating techniques and good systematic fieldwork, archaeologists are beginning to understand the chronology and complex development of burial-ritual monuments and the landscapes they inhabit (e.g., Edmonds 1999; Thomas 1999).

Irish passage tombs (or graves), in use between the fourth and third millennium BCE, form part of a much wider Atlantic sequence that probably has its origins in the Iberian Peninsula (Shee-Twohig 1981; Grogan 1991; Nash 2012). They are arguably the most noticeable Irish monument group and number around 220, although only 50 contain passage grave art (Waddell 2005: 74). They are usually clustered in groups forming cemeteries and are distributed in a distinctive northeast/southwest band across central and Northern Ireland.

Along with the Boyne Valley complex, the two passage tomb clusters at Loughcrew and an array of Neolithic monumentality including the Mound of the Hostages occupy the Hill of Tara (Co. Meath) and make for a busy ritual presence within this part of Ireland (Stout 2003; O'Sullivan 2005). This distinct architectural form usually comprises a circular (sometimes subcircular)

mound which is delineated by a stone kerb. Mounds vary in size, between 10 and 85 m in diameter, and usually cover an east–west oriented passage (ranging between 1 and 40 m in length) that leads from a facade/entrance to a chamber, deep within the heart of the mound. It is on components such as the kerbing, passage, and chamber where a unique prehistoric rock art tradition is engraved, sometimes referred to as *passage grave art* or *megalithic art* (Shee-Twohig 1981; Eogan 1986). This sometimes hidden signature is a non-representational repertoire and comprises geometric and curvilinear motifs such as chevrons, concentric circles, spirals, and zigzags; no two panels across the entire assemblage are the same, each stone reflecting a unique narrative (Lynch 1973; Shee-Twohig 1981; Eogan 1986; O'Sullivan 1986, 1993; Cochrane 2006; Nash 2006). Many motifs present within the larger monuments are distinctively regionalized such as the double and triple spiral and the radial variants found in at Newgrange or the crescents and serpentiniforms from Knowth. Analysis has identified certain areas of the monument that contain either curvilinear or rectilinear motifs (see in particular by Elizabeth Shee-Twohig 1981; George Eogan 1986 and Muiris O'Sullivan 1986, 1993). Closely associated with rock art and the architecture is the way that the dead are brought to the monument and where they are deposited, along with the grave goods that accompany them. Throughout the passage grave tradition where preservation allows, burial rites and symbolic behavior as shown through the artifact assemblages appear to be identical, passage tombs acting as repositories for successive generations of people, each mound representing a periodic corporate act of internment.

Key Issues/Current Debates/Future Directions/Examples

Signaturing Landscape

The 35 Neolithic monuments, standing within a postmedieval agricultural landscape, occupy the northern river terrace gravels (regarded as highpoints within the valley landscape) and ridges of a bend within the Boyne Valley, County Meath, central-eastern Ireland. The bend in the River Boyne, designated a World Heritage Site in 1993 (Referred by UNESCO to as an *Archaeological Ensemble of the Bend of the Boyne*), appears to enclose this landscape of over 785 ha. Here, the course of Boyne appears to physically separate ritual space immediately north of its banks from secular space to the south during a time when the passage tombs are the focus of extraordinary community activity. However, secular monuments in the form of circular stock enclosures and evidence of settlement, located among the ritual monuments, probably represent earlier and later utilization of the landscape before and after passage tombs are in use (Eogan 1991).

The monument group, comprising mainly passage tombs of varying size and clustered into four distinct groups, is one of Western Europe's most concentrated and has as its foci three massive circular or ovoid stone chambered Neolithic passage tombs – Dowth in the east, Knowth in the west, and Newgrange in the central part of the bend (Fig. 1) (O'Kelly 1982a, b; Eogan 1986). Apart from these monuments, this ritual complex is also home to an array of smaller [satellite] passage tombs, monoliths (standing stones), later post-passage grave henges and earthen enclosures (Stout 1991), and evidence of pre- and post-passage grave settlement. Early pre-cairn Neolithic settlement is witnessed with the excavation of longhouses located within the northern part of the Knowth site, dated to around 3900 BCE. Prior to the construction, between 3300 and 2900 BCE, later settlement then shifts to the western part of the site with the construction of further longhouses (Eogan and Roche 1997; Cooney 2000). Concerning the Late Neolithic post-cairn ritual landscape, enclosures and henges would have indelibly stamped their presence on the Late Neolithic landscape.

Establishing Monumentality

The monuments that occupy the northern terracing of the Bend of the Boyne are arranged into four clusters; three of these center around the three large passage tombs, while a fourth linear cluster stands between Dowth and Newgrange.

Palace of the Boyne (Brú na Bóinne), Fig. 1 The distribution of the Boyne Valley group of monuments including the passage graves of Newgrange, Knowth, and Dowth

The largest and arguably the most impressive of the three passage tombs is Newgrange (Gaelic: *Sí an Bhrú*). This circular stone, earth- and turf-constructed monument was built between 3295 and 2925 cal BCE, at a time when there were a large number of passage grave monuments being erected around the Neolithic core areas of Atlantic Europe (Grogan 1991: 126). Its dominance, standing on a small ridge along with a series of enclosures, standing stones, and tumuli within the Boyne landscape, would have probably provided the pilgrim with an obvious visual and ritual focus (Fig. 2) (O'Kelly 1982a, b).

The slightly oval mound measures 85.3 m in diameter and stands 12 m, covering a total area of around 0.45 ha. The central section of the cruciform chamber has a corbelled vaulted roof that extends some 3.5 m into the core of the mound, while the roofs of the side chambers have flat slabs. The long passage is constructed of 43 upright stones (21 on along the eastern side and 22 along the western wall); some of these are decorated with carved abstract images. Outside, the mound is delineated by 97 kerb stones made of local grit (graywacke) or slate and each decorated on both the external and internal surfaces with carved rock art. Based on the seminal work of Shee-Twohig (1981), Newgrange has up to ten types of motif that include curvilinear (arcs, circles, cupmarks, cup-and-rings, serpentiniforms, and spirals) and rectilinear forms (chevrons, lozenges, radials, parallel lines, and offsets); Knowth is similarly embellished.

Over its long history, Newgrange underwent a number of phases of use and abandonment. Similar to other passage tombs elsewhere, Newgrange is constructed using a tried and tested blueprint that includes four major architectural elements: circular mound, entrance/facade, passage, and chamber. These primary architectural elements

Palace of the Boyne (Brú na Bóinne), Fig. 2 Newgrange from the Boyne. (Image: G.H. Nash)

are arranged in such a way to make the architecture of Newgrange unique (Nash 2006). According to Michael O'Kelly, the archaeologist responsible for excavating Newgrange, some of this architecture is aligned to ritually acknowledge a number of celestial and cosmological events such as the winter solstice. An extensive archaeological excavation of Newgrange revealed a number of unique traits including a roof-box above the main entrance, abstract passage grave rock art both inside and outside the monument, and a 19-m-long east–west passage that was deliberately constructed in such a way to restrict the visual access between the entrance/facade and the cruciform chamber, a trait repeated in passage grave monuments throughout the Neolithic. The roof-box, unique to the European passage grave tradition, was possibly constructed in order to allow a beam of light to penetrate the back of the chamber during the midwinter solstice (Lynch 1973: 152).

One of the earliest detailed archaeological plans of the three passage tombs was made by Welsh antiquarian Edward Lhwyd in 1699. Lhwyd was alerted when farm laborers discovered the entrance at Newgrange when digging the mound for stone, and as a result, he made a detailed plan of the internal arrangement of the passage and chamber areas. Following in the footsteps of Lhwyd were a number of antiquarians who undertook various pieces of work both inside and outside the monument, some suggesting that the monument was constructed during the early medieval period by marauding Vikings; others considered the ancient Egyptians as the builders. Between the time of Lhwyd and until it was taken under the control of the state (then, the United Kingdom of Great Britain and Ireland) in 1882, the monument and the surrounding landscape had been under great threat, mainly the result of vandalism and farming practices. Following statutory protection, Newgrange underwent a significant conservation program in 1890 under the directorship of Thomas Newenham Deane. During the early to mid-twentieth century, Newgrange was investigated a number of times in order to establish its construction methodology and date. It was still considered at this time as a Bronze Age monument rather than Neolithic. Throughout this period and in addition to the intense archaeological activity, the site had become a focus for tourism (e.g., Macalister 1939), and as a result, electric lighting was installed in the passage area during the 1950s. The site also became a local tourist attraction with numerous visitors leaving their mark, usually in the form of graffiti. To some, the entrance became an evocative statement of a bygone megalithic age (Fig. 3). The largest and most comprehensive investigation of the site was undertaken by Michael O'Kelly between 1962 and 1975 where a sporadic sequence of prehistoric activity, from the Late Mesolithic (Residual (disturbed) Late Mesolithic flint tools have been recovered from Bronze Age Beaker context from Newgrange (Cooney 2000: 30) to the Iron Age and beyond, was unearthed.

Following O'Kelly's exhaustive excavation program, the site was controversially restored. During excavation, white quartzite was found in high concentrations around the base of monument, in front of the kerbing, either side of the

Palace of the Boyne (Brú na Bóinne), Fig. 3 Photograph taken by nineteenth-century photographer R. J. Welch of the entrance and the decorative sill stone

façade. O'Kelly considered the white quartzite stones to have originally been fixed to the near-vertical mound walls, and as a result of this, the restoration program fixed a wall of white quartzite stones and river cobbles to a steel-reinforced concrete retaining wall that surrounds the eastern section of the mound, including the area around the façade. This extremely obvious display of this section of the mound arguably contradicts the concept of restricting the visual access of the monument (Nash 2006). Moreover, a similar deposit was found around one of the entrances to Knowth. Eogan, the archaeologist responsible for excavating Knowth, considered the quartzite deposit to be a ritualized pavement (Eogan 1986: 47).

At the extreme east of the bend and standing on a short oval ridge, around 250 m east of the Boyne, is Knowth (Gaelic: *Cnobha*). The ovate-shaped mound measures 81 m by 95 m and is delineated by 127 decorated kerbstones. Unusually for the European passage grave tradition, there are two passages leading to two chambers (entered from the east and west), both discovered through excavation in 1967 and 1968 by George Eogan's team who originally started investigating the site in 1962. (The site was briefly investigated by R.A.S. Macalister in 1941.) Surrounding the monument are at least 18 smaller satellite passage tombs of varying shape and size (Eogan 1986). According to a useful synthesis by Cooney (2000: 83–85) based on investigations by Eogan and Roche (1997), the satellite monuments developed soon after the construction of Knowth, probably around 3000 BCE.

The slightly ovate mound supports two diametrically opposed chamber and passage arrangements, one entering from the eastern side of the mound and the other from the west; both aligned on the March and September equinoxes (Eogan 1986: 178). The eastern chamber is cruciform in plan and is connected by a 35-m-long passage, while the undifferentiated western chamber has a 32-m-long passage. Carved on much of the stone, including those surfaces that face inward toward

Palace of the Boyne (Brú na Bóinne), Fig. 4 Mid-nineteenth-century engraving of Dowth prior to excavation in 1847 by W.F. Wakeman and published in his *Handbook of Irish Antiquities* (1848)

the mound, is an array of passage grave art. Archaeologists have also uncovered a white quartzite pavement around the eastern façade area as well as granodiorite, a phaneritic igneous rock found in other parts of the monument. The visual display of the rock art, the color symbolism of the quartz pavement, and other elements would have carried religious meaning.

Dowth (Gaelic: *Dudhadh*), the least-investigated of the three passage tombs, was probably constructed around 2500 BCE (Fig. 4). The mound, measuring 85 m in diameter and standing over 15 m in height, sits on one of the highest points within the Bend of Boyne's landscape. From the top of the mound, there is clear intervisibility with Knowth and Newgrange. Similar to the other two passage tombs, the mound at Knowth is delineated by a series of kerbstones, some of which are engraved with passage tomb art. Within the vicinity of the entrance and façade is evidence of a white quartzite pavement. The mound was unceremoniously excavated in 1847 under the direction of county surveyor R.H. Frith (on behalf of the Royal Irish Academy), the result being much of the western section of the mound being completely removed, and no official records of the excavation were made. Before work commenced, a curious building known as the *gala music room* was demolished. This building had stood on the summit of Dowth since before 1775 (Harbison 2007) (present on Gabriel Beranger's copy of an engraving of 1775).

Constructing the Boyne Landscape

We are somewhat fortunate that two of the three giant passage tombs within the Bend of the Boyne have been excavated in recent times, both applying modern archaeological excavation techniques. Furthermore, and as a result of these recent excavations, there have been a number of useful discussions concerning their origin, use, demise, and the landscape in which they sit (Cooney 2000). There is a clear chronological development of the secular and ritual landscapes that commence from the Late Mesolithic/Early Neolithic through to the demise of the passage grave tradition during the Late Neolithic. This heavily ritualized landscape is later replaced by a subtle, less commanding landscape of the henge and enclosure. The use of the natural topography along with the physicality of the River Boyne clearly shows an intentionality

to enclose a ritual landscape, possibly separating ritual from secular activity.

The monuments themselves appear to act as a catalyst for ritual and symbolic behavior, the landscape being the backdrop. Both the dead and the living would have each participated in the ritual in and around each monument, the dead as passive participants embarking on a journey to another world. While in the monument, probably the dead would have understood the rock art narrative on each of the kerbstones that faced inward toward the mound, their realm, their art (Nash 2006). The audience located outside the monument, within the facade area, would have caught their last glimpse of the body as it entered the realm of the dead. The passages at Newgrange and Knowth slightly constrict in size in order to restrict the visual access to the ritual activity that would have occurred within the inner passage area, where much of the rock art is engraved, and also to the chamber. Limited archaeological evidence indicates that as the body passed through the passage to its temporary resting place – the chamber – the rock art would have played an integral role in legitimizing the activity within this part of the tomb. Accompanying the body would have been an array of engendered grave goods, some of them prestige items such as mace-heads and axes. These items, along with daily perishable commodities such as food, would have assisted in the successful transition between the liminal world where body has a name and face to a world where only the meta-physical remains can gain access. The ongoing use of each monument over time created an ancestral cult and embodied the legitimacy of each monument and the landscape in which they stand.

Palaeopathology: The Study of Ancient Disease in Archaeological Human and Nonhuman Remains

Charlotte Roberts
Department of Archaeology, Durham University, Durham, UK

Introduction and Definition

The World Health Organization defines health as "a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity." This definition has not been amended since 1948 (http://www.who.int/suggestions/faq/en/, accessed July 26, 2017). This of course is a definition that relates to living populations but could be equally applied to the past. Being unhealthy today compromises normal life and the very function of society; this would have been true for our ancestors all over the world.

How can we study our ancestors' health? It is possible to access information pertinent to health and disease in the past by studying historical documents describing disease, and viewing artistic representations of disease in particular periods in time (e.g., Fig. 1). In prehistoric times, these types of evidence are relatively nonexistent and they are more useful for more recent periods, for example, the medieval period in Europe. Our primary form of evidence for disease and injury in the past comes from human remains excavated from cemeteries and other funerary contexts dating from when the earliest humans appeared on the planet (Fig. 2). This study is named "palaeopathology" and is defined as the study of disease in the remains of both human and nonhuman remains, as first defined by Marc Armand Ruffer in 1910 (Aufderheide & Rodríguez Martín Aufderheide and Rodriguez Martin 1998: 5–6). The evidence for human disease is a subdiscipline of "physical or biological anthropology" which, in turn, is a part of the discipline of "Anthropology" (Roberts and Manchester 2010; Buikstra and Roberts 2012). The Paleopathology Association provides the infrastructure for people working in this field, an Association based in the United States that has its origins in 1973 (https://paleopathology-association.wildapricot.org/; accessed July 26, 2017).

Palaeopathology: The Study of Ancient Disease in Archaeological Human and Nonhuman Remains, Fig. 1 Sculpture showing possible tumor on left eye

While most work in the early history of palaeopathological study was on animal remains, now there is much more work focused on humans rather than other animals. Much of the early (human) work concentrated on evidence of disease in individual skeletons ("case studies"), but over the last 50 or so years there has been much more of a trend towards looking at "population" health and the consideration of larger groups of skeletons from specific funerary contexts (e.g., see DeWitte and Bekvalac 2010). However, "case studies" can provide invaluable information about the presence of a disease in a particular geographic context and time period, but the data cannot be applied to understand general population health in that place

Palaeopathology: The Study of Ancient Disease in Archaeological Human and Nonhuman Remains, Fig. 2 Medieval cemetery

and/or time (e.g., see Lefort and Bennike 2007). One quite recent development is more of a focus on the individual and detailed studies of single skeletons or preserved bodies, stimulated by the research of Tilley and the "Index of Care" (Tilley and Schrenk 2017). In more recent times, there has also been a focus on bringing together large amounts of data to study the history of specific diseases, and the application of newly developed methods to diagnosing disease in human remains (see below). Most human remains that palaeopathologists study consist of skeletons, and therefore any disease that only affects the soft tissues of the body will not be seen, unless more advanced analytical techniques are used, for example, ancient pathogen DNA analysis to detect infectious disease. Not only are historical documents and artistic representations in this instance invaluable to access information about diseases that do not affect the skeleton, pathogen DNA analysis is starting to detect those soft tissue diseases.

A key factor to remember in utilizing the evidence of disease in human remains to reconstruct the origin, evolution, and history of disease is to place the data in archaeological context, termed the bioarchaeological approach (Buikstra and Beck 2006). For example, if there is evidence of pathological change on ribs indicating a high rate of respiratory infection in a population then it is essential to explore what type of living conditions the population experienced, how many people lived in the community and its density, and whether the housing conditions would have predisposed to poor air quality, including the possibility that airborne infectious pathogens could be transmitted easily. By using archaeological evidence of settlements and housing, it is possible to assess how living conditions prevented or put at risk the community's inhabitants. Using a bioarchaeological approach is the key to understanding why and when diseases appeared in populations at specific times. It also enables a "themed" approach to be taken, by concentrating on using the pathological evidence to discuss particular "themes" such as diet and economy, work, indoor, and outdoor living environment, access to health care, and the impact of age, sex, gender, ethnicity, social status, migration, and climate on health within those broad themes (Roberts 2009: Chap. 6).

Palaeopathology is a thriving discipline which also has synergy with evolutionary medicine, a growing field (Stearns & Koella 2008). It contributes the time depth to studying disease that medical doctors today cannot hope to achieve when diagnosing and treating patients with disease usually over relatively short time periods. It also provides data on how bones and teeth are affected in disease in people who did not have effective therapies, and sometimes the pathological changes

recognized in skeletal remains are invisible to doctors today because the changes are too subtle to even detect with radiographic techniques (e.g., Lambert 2002).

Key Issues

How Are Pathological Conditions Studied in the Archaeological Record?

The focus now is on skeletal remains. Disease is recognized in the skeleton by bone formation and bone destruction, or a mixture of the two. Teeth may also be destroyed, for example, in dental caries (Fig. 3), and dental disease can be accompanied by bone formation and destruction of the jaw bones. Bone formed may be classified as "woven" or lamellar" (Figs. 4 and 5). In the former, the bone is immature, porous, and disorganized, indicating the disease process was active at the time of death of the person; the latter is smoother and more organized and indicates the person survived for some time with a disease such that the initial woven bone was transformed into healed lamellar bone. Lamellar bone indicates evidence for chronic disease. These changes are recorded for each skeleton and then their distribution pattern considered, bearing in mind that not all skeletons are completely preserved. It is known in the clinical record that diseases affect the skeleton differently. For example, the autoimmune disease rheumatoid arthritis affects the synovial joints of the neck vertebrae, and of the hands, feet, shoulders, elbows, wrists, and knees, symmetrically (Resnick 1995), and in the bacterial infection tuberculosis, destructive lesions of the lower spine, hip, and knee joints are most commonly seen. Differential diagnosis for lesions detected in each skeleton must be discussed because the skeleton can only be affected by disease in a limited number of ways (bone destruction or formation); so several diseases may be possible diagnoses for the bone lesions seen, especially if the skeleton is fragmentary and the total distribution of bone changes cannot be observed. However, while there are clinical data that provide these characteristic bone changes and distributions for each bone disease, it has to be assumed

Palaeopathology: The Study of Ancient Disease in Archaeological Human and Nonhuman Remains, Fig. 4 Woven bone formation on calcaneum, or heel bone

Palaeopathology: The Study of Ancient Disease in Archaeological Human and Nonhuman Remains, Fig. 5 Lamellar bone formation on long bone

that the changes and their skeletal distribution have not changed throughout time. Standards for palaeopathological data collection have been developed so that data are collected in the same way by all palaeopathologists; this means that valid comparisons of data can be done (Buikstra and Ubelaker 1994; Brickley and McKinley 2004). Other methods of diagnosing disease in skeletal remains are also used, including histological, radiographic, and biomolecular analyses, and it is the data derived using these methods that are developing more nuanced diagnoses and interpretations that are having an impact on our further understanding of the history of disease.

Following collection of the data, disease frequency rates are produced and, by linking these rates to contextual data from each site, this will show how common or how rare certain diseases were for that population compared to others, perhaps of the same time period and geographic region (and why), but also for different time periods and regions. For example, a study of fractures to bones of people who lived in Medieval British urban contexts varied from 0.3% to 6.1% of the total bones examined for each of six sites, with the highest rate being seen in London and the lowest at a site in Scotland. Thus, it can be seen that, even in the same (urban) context, injury rates can vary and this will be related to similar and different risk factors specific to particular sites and regions. Along with using archaeological data, to interpret the disease patterns seen, contemporary medical historical information may be available. Palaeopathologists are also increasingly using medical anthropological research to inform their findings, medical anthropology being the study of health and disease often in traditional living communities and usually in developing countries. They are also beginning to work alongside scholars from evolutionary medicine (e.g., Trevathan et al. 2008), a discipline that will benefit more and more from the deep time approach of palaeopathology.

What Are the Limitations to Palaeopathology?

Wood and colleagues' "Osteological Paradox" paper (1992) provided an opportunity for palaeopathologists to reflect on their discipline, a paper that is as relevant today as it was in 1992. They highlighted a number of problems with inferring health from the skeleton: the impact of the state of preservation of the skeleton on what can be recorded, the fact that soft tissue diseases cannot be detected, that people may have died before bone changes could occur, that often small samples of skeletons are being studied and their representation of the living population is questionable, and that there was a focus on individual skeletons rather than larger skeletal samples. They also emphasized that those with evidence of disease were the "healthy" people, i.e., those who had survived the acute stages of a disease and lived long enough for bone damage to occur and become "healed". They furthermore pointed out that it was not possible to detect individual variation in risk of disease and death using skeletal samples, and that the sample studied had undergone selective mortality, i.e., they were the dead part of the original living population – so how representative of the living were they? Other factors to be considered was the nonstationary nature of populations (in- and out-migration), the lack of nonadults in most samples (thus negating much inference about the health of that portion of society), the subjective nature of ageing adults and the problem of estimating sex of nonadults, the lack of information about cause of death (it is only usually possible to suggest what people suffered during life), that pathological bones are fragile and may deteriorate in the ground and not be excavated or analyzed, that it was important to be able to detect postmortem changes versus pathological ones, and also that skeletal features may represent normal variation. This long list of challenges perhaps suggests that there is not much point in spending too much time on palaeopathology but, while Wood et al. (1992) is still very current and is required reading for all palaeopathologists, there have been developments that have addressed some of their concerns.

Those developments include emphasizing the importance of providing true prevalence rates for disease, i.e., how many bones or teeth observed have changes attributable to specific disease processes, which can account for poor preservation of skeletal remains. This goes alongside providing

individual frequency rates, i.e., how many skeletons with a particular bone of interest preserved has evidence for disease (see Roberts and Manchester 2010: 9–10). Bayesian analyses are also helping to more accurately reflect the ages of adults as well as produce more realistic frequency rates for disease. The increase in ancient pathogen DNA analysis to detect and diagnose disease in skeletal remains means that soft tissue diseases can potentially be identified. DNA analysis in the living can also provide an indicator of genetic risk of disease; it is anticipated that this is an area that could see development in bioarchaeology. DNA analysis can also be used to estimate the sex of nonadult human remains. Larger sample sizes are also now studied which means that the data on disease are, in theory, more representative of the disease experience of the general population. Furthermore, stable isotope analysis to explore mobility in bioarchaeology will increasingly provide information on how mobile people were in the past and whether that mobility could have potentially affected the demographic and morbidity profiles of the dead population being analyzed. Additionally, there has in recent years been more of a focus on the nonadult part of the archaeological past which has led to the seeking out of cemetery samples that represent that section of society. Better training of bioarchaeologists has further led to the more reliable differentiation of antemortem, perimortem, and postmortem skeletal changes, although poor preservation of pathological and nonpatholoigcal bones remains a challenge.

Past and Current Work, Including Debates

Initially, most work in palaeopathology consisted of "case studies," as discussed above, which is still the case, although population based work is much more common. Some parts of the world have contributed exponentially more information about the history of disease than others, for example, the United States and United Kingdom. "Case" and "Population" studies both have their part to play in palaeopathology, but it is the latter that provides a broader view of past health at the population level. In addition to studies of individual and population health from around the world, there have been some studies of health through time in particular countries or continents. In many of these broader studies there appears to have been a decline in health through time as societies became more complex. Palaeopathological studies now frequently aim to answer specific questions or test hypotheses about health, based on what is known about the prehistory or history of a specific population or place; this might be to consider the effect of a transition such as from hunting and gathering to agriculture or from rural to urban living. Scholars have also focused on specific diseases to explore their origins and histories, often using a range of disciplines to come to conclusions.

Finally, and increasingly, palaeopathologists are using a suite of analytical methods to generate data on health that was simply not possible before these methods were used. For example, as discussed above, ancient pathogen DNA analysis since 1994 has allowed scholars to diagnose soft tissue diseases, diagnose disease when the person died before bone changes could occur, and even more recently explore the origin and evolution of the organism that caused the bone changes. Stable isotope analyses for exploring diet and mobility are also making it possible to link disease with diet and mobility to assess their impacts on whether a person or population contracted disease. Advances in imaging and histological techniques are adding to the methods used for disease diagnosis and, furthermore, palaeopathology now utilizes archaeological and historical contextual data to interpret biological data for disease much more than in its early years. There remain debates about the validity and ethics of doing destructive analyses of precious skeletal remains, whether data emanating from a DNA analyses are verifiable, and about the origin of diseases (e.g., venereal syphilis).

Future Directions

As destructive analyses increase in bioarchaeology while scholars strive to discover more about their ancestors' health, there is increasing repatriation and reburial of skeletal remains

around the world (Roberts 2009: Chap. 2). However, it is without doubt that these destructive techniques will continue to be used, and for ancient pathogen DNA analysis there are now important studies focusing on the evolution of organisms and strains of those organisms (e.g., Bouwman et al. 2012). However, basic macroscopic data collection will remain the mainstay of palaeopathology because, without it, there is no possibility of interpreting the data derived from those destructive analyses. Furthermore, more advanced analytical techniques are expensive, particularly for multiple samples analysis and most scholars do not have access to either the facilities or the money to do such large scale research. Costs will, nevertheless decline as time passes. With increased repatriation and reburial, it is imperative that skeletal collections are used more widely than is currently the case and databases of curated collections should become established to enable scholars to seek out the most appropriate human remains to answer their questions (see Roberts and Mays 2011). It is also without doubt that the trend is to look at the big picture of past health whereby very large datasets are being collected which provide a much more nuanced view of health over long periods of time and large areas of the world, as seen in the Global History of Health Project (http://global.sbs.ohio-state.edu/). Palaeopathology has provided a wealth of information about the health of our ancestors through their remains but there is much more to come in the future.

Paleoanthropology Society

John Yellen
Archaeology Program, National Science Foundation (NSF), Washington, DC, USA

Basic Information and Major Impact

The Paleoanthropology Society was founded in 1991 and held its first annual meeting the following year.

It has twin goals: the first, to foster research which furthers understanding of human evolution and the second, to build an international community of researchers and interested individuals who enjoy collaboration and participation in the creation and advancement of such knowledge.

The society is built on the understanding that multiple factors – biological, behavioral, and environmental – must be taken into account to gain insight into how the human species evolved and that research best proceeds through the interaction of researchers in many disciplines. Biological anthropologists, archaeologists, geologists, paleontologists, and cognitive scientists, as well as other specialists have participated in and contributed to annual meetings which include both posters and oral presentations in nonconcurrent sessions. Abstracts for presentation are evaluated through peer review and submission instructions are included on the Society's open access web site, www.Paleoanthro.org.

The Society publishes an online electronic-only journal, *PaleoAnthro*, which is accessible free of charge through the Society's web site. The society meets annually, normally in alternate years, with the Society for American Archaeology and the American Association of Physical Anthropologists. Membership is open to all interested individuals, the majority of whom consist of graduate students and Ph.D. researchers both within and outside the United States. Annual dues and meeting registration fees are purposely kept low and income above expenses is used to subsidize participant meeting attendance. The Society is incorporated in Washington DC and is recognized under US law as a tax-exempt scientific organization.

Paleoart Studies: Scientific Methods

Robert G. Bednarik
International Federation of Rock Art Organizations (IFRAO), Melbourne, VIC, Australia

Introduction

Most of the world's surviving paleoart (art-like productions of preliterate societies) occurs in the form of rock art, which is found in nearly all countries of the world. Its study by scientific methods is a historically recent development, especially of the last three to four decades. In this short time, the scientific methodology applied to rock art has evolved with the help of several disciplines. Foremost among these are nuclear physics, forensic science, geochemistry, geomorphology, conservation science, ethnography, and semiotics, but many others have also contributed. As a result a number of specific approaches have been developed. This emerging methodology is briefly defined here.

Because of the perceived need to integrate rock art in archaeological constructs or narratives, it has long been a high priority to ascertain its age. The archaeologically favored method, excavation and age estimation of sediments concealing rock art, has several limitations. Over the past 120 years, archaeological excavation has succeeded in only 22 instances in providing credible minimum antiquities by this method. The age of a sediment deposited after the creation of rock art can at best offer minimum ages, and these may be very conservative. Moreover, these determinations depend upon a chain of unfalsifiable deductive propositions: that the sediment has not been subjected to disturbance or redeposition; that the dating criterion actually relates to the event of deposition (e.g., charcoal used in radiocarbon analysis may have been dislocated through turbation, quartz grains used in OSL analysis may have been displaced without exposure to light occurring, etc.); and that the dating method has yielded valid results (Bednarik 2001).

One of the rationales of the scientific approach in rock art research is to supplement this indirect dating method with direct methods, which are defined by direct physical relationships of rock art and dating criterion and the formulation of falsifiable propositions concerning this relationship.

Definition

The epistemology of rock art science requires that all propositions be rendered testable and that interpretations not be dependent upon etic assumptions in the absence of emic evidence. This narrows the range of admissible practices and methods, of which those listed below have so far been pursued. Ultimately, most are in some fashion reminiscent of the techniques of forensic science (Montelle 2009) (Fig. 1). This definition excludes, for instance, reliance on interpretations of rock art (on what it supposedly depicts), and on etic taxonomies of it, such as those based on perceived styles, or on the statistical treatment of non-representative samples. Therefore one of the pivotal principles in a scientific paradigm is to treat all rock art as taphonomic residue, whose quantitative properties are determined by taphonomic logic (Bednarik 1994a) rather than by the characteristics inherent in a living tradition.

Key Issues/Current Debates

The demand in direct dating of rock art for secure physical relationship between the rock art and the dating criterion is illustrated by the following example. The bulk radiocarbon content of rock paint residues is in most cases not an acceptable criterion, because all rock surfaces and surface deposits contain organic matter of many different types, as do all mineral accretions over or under petroglyphs. Such dates are only viable if they derive from materials sealed in by impervious deposits (silica or oxalate), or if the analyzed matter is identified at the object or molecular level. The latter condition has only been met once so far (Ponti and Sinibaldi 2005). The most reliable carbon dates are those from beeswax

Paleoart Studies: Scientific Methods, Fig. 1 Example of forensic work: determining the tools used in the creation of deep cupules in a cave (Ngrang Cave, Victoria, Australia; photo by Yann-Pierre Montelle)

figures (so far only reported from northern Australia), followed by charcoal pictograms. Radiocarbon dates from paint residues dominated by mineral pigment are not credible, because the dating criterion's (carbon age of unknown matter, in this case) relationship to the age of the paint cannot be demonstrated.

The nano-stratigraphy of paint residues or mineral accretions is determined by microscopic excavation of very thin layers (Fig. 2), either for chemical analysis of strata or their radiometric dating (Bednarik 1979; Watchman 1992). It has been applied to ferromanganese accretions, carbonates, silicas, and oxalates, providing testable data for age estimation and other scientific information about rock art. Similarly, the analysis of the composition of, and inclusions in, paint residues (such as brush fibers or pollen; Cole and Watchman 1992) can provide a wide range of empirical information about rock paintings and of the circumstances of their production.

The most promising methods of determining the age of petroglyphs utilize variables of geomorphology providing sequential contexts. Each rock panel features numerous forensic traces of events and processes, some of which may be datable, and each rock art motif is situated within a chronological framework they provide. Exfoliation or spalling scars, macro-wanes, fissures, patination, weathering rinds, glacial striae, fluvial or marine wear, and fire or lightning damage are among these traces and need to be recorded, locating the rock art within their relative sequence. Some of these processes, such as rock surface retreat and microerosion, are amenable to quantification. The latter involves microscopic erosion criteria (Fig. 3), including the micro-wanes gradually forming on fracture edges of mineral crystals (Bednarik 1992) or the relative retreat of a more soluble rock constituent (such as the colloid silica cement of sandstone). Both this dating method and the estimation of fluvial degree of erasure of low-grade metamorphics by suspended load in rivers (Bednarik 2009a) have been calibrated against sidereal time, providing sound approximations of petroglyph ages.

Another promising method is colorimetry of ferromanganese accretions on petroglyphs (Fig. 4). The gradual colonization of rock surfaces by patina-forming matter appears to be a relatively constant and regular process as a function of time (Bednarik 2009b). The detection of splattered paint in sediment below rock painting panels or of mineral dust and fractured grains deriving from the production of petroglyphs seem comparatively less promising.

The technology of rock art – how it was made – is an important aspect of rock art science (Bednarik 1998). It proceeds primarily by forensic methods in tandem with replication studies and gestural research (biokinetics). Especially the intensive study of impact or abrasion marks in petroglyphs can lead to propositions about technology that can then be subjected to testing by replicating the traces under controlled conditions. This can yield information about the tools used; the direction and energy of impact or abrasive action; and, in combination with spatial aspects and accessibility of rock panels, about the circumstances of production. Similar considerations apply to rock paintings, drawings, and stencils, albeit to a lesser degree. Replicative studies of considerable variety have been attempted, and they form one of the principal approaches of scientific rock art research.

Paleoart Studies: Scientific Methods, Fig. 4 Calibrated colorimetric study of differences in petroglyph patination indicating differences in age (Najd Sahī, Jabal al-Kaubab East, Saudi Arabia; photo by author)

The discrimination of anthropic from natural rock markings has engendered much confusion in the past. Particularly the separation of petroglyphs from numerous types of natural and even other humanly made rock markings resembling them requires specialist attention, notably when relatively simple markings are involved (Bednarik 1994b). Potholes, sandstone erosion pits, and solution scallops in caves have been mistaken for cupules (Fig. 5); animal scratches and other limestone cave features have been interpreted as cave petroglyphs; and anthropic marks such as bulldozer scrapes, steel cable grooves, and core drill circles were described as open-air petroglyphs and natural coloration of rock surfaces as rock paintings; the latter was even radiocarbon dated in one case. This frequent confusion of natural rock markings with rock art is of concern because there is no value in treating such phenomena as rock art and then inventing meanings for them.

Only a small proportion of surviving paleoart consists of portable material. Some of the methods specifically developed for this corpus, especially traceology (the microscopic study of abraded or incised marks), have been successfully adopted by rock art science; other technological analyses are specific to mobiliary paleoart. Traceology derives from "internal analysis" as developed by Marshack (1972) to examine suspected notations and other incised markings on Paleolithic portable objects. Besides its application to engraved plaques, microscopy also provides the most important analytical tool in the scientific study of beads, pendants, and figurines and is crucial in the detection of fakes and misidentifications. This can include the identification of a wide variety of taphonomic markings, such as those acquired by transport or caused by plant rootlets on carbonaceous materials. In the scientific analysis of portable paleoart, replication is again of particular importance (Bednarik 2001).

Future Directions

The recording of rock art has come a long way since the iconographic, interpretation-driven endeavors of the past. It now involves a rapidly evolving and complex methodology based on state-of-the-art technology (e.g., Plets et al. 2012; López Fraile et al. 2016). To be comprehensive and scientifically relevant, it needs to provide not only the most accurate record of the rock art but also of all other traces preserved on the rock panel (Soleilhavoup 1985). Such detail is required

Paleoart Studies: Scientific Methods, Fig. 5 Pothole surrounded by cupules and other petroglyphs (Bola Chanka, Santivañez petroglyph complex, Bolivia; photo by author)

not only for realistic evaluation and empirically based interpretation but also for the purposes of conservation and preservation science. This field has since the 1980s advanced from a commonsense approach to a scientifically based discipline with its own extensive methodology (Rosenfeld 1985). It is also developing rapidly and is becoming increasingly important in view of the ongoing degradation of all of the world's rock art. Different conservation methodologies are being designed for open-air sites and deep cave sites, because the environmental constraints differ inherently between these two site types.

The scientific study of rock art draws heavily on many of the hard sciences, but it is a relatively new approach and remains in a comparatively embryonic state. Nevertheless, it has emerged as a discipline in its own right and is likely to develop in unexpected directions. Most of the work so far is much in need of refinement and standardization, and a sound epistemology is not sufficient to have a significant practical impact. It needs to be translated into new methods and approaches. Some of the most exciting recent developments are the endeavors to introduce scientific fields such as the cognitive and neurosciences. This approach is likely to center on the role of exograms, the memory traces stored outside the human brain. From a scientific perspective, the most important aspect of paleoart is that it represents the only comprehensive and dependable source of information about the cognitive evolution of hominins. That potential has so far remained almost unexplored. This is one development suggesting that, rather than serving as a source of etic archaeological narrative, rock art and other paleoart need to serve a variety of other disciplines if their full research potential is to be realized.

Paleoentomology: Insects and Other Arthropods in Environmental Archaeology

Philip I. Buckland[1], Paul C. Buckland[2] and Fredrik Olsson[3]

Introduction

Insects are the most diverse group of animals on the planet and as such are present in a wider variety of habitats than most other complex organisms. This diversity, in addition to a long evolutionary history (Grimaldi and Engel 2005), and together with a propensity to be preserved in both desiccating and anaerobic environments, has provided an excellent tool for the reconstruction of both Quaternary and more immediate archaeological environments. Insect remains often provide proxy environmental information on the immediate context from which the fossils are derived, and as such may be either complementary to the more regional picture provided by palynology or indicate site conditions, such as levels of hygiene and evidence of trading connections, which are rarely available from any other palaeoecological source. They therefore provide information on a broad range of habitats and conditions, on- and off-site, and in addition, in appropriate contexts, also climate. Processing of samples is essentially simple, requiring readily available materials, yet is time consuming, and identification of the usually disarticulated fragments (sclerites) requires diligence and patience and access to well-curated reference collections. Fortunately, abundant literature, computer software, and database tools now exist to aid in their interpretation.

Definition

Paleoentomology is the study of fossil insect remains, often with the intention of examining evolutionary changes, while more specifically Quaternary (paleo-) entomology generally has aims toward understanding environmental, climatic, and/or cultural conditions in the past, from both archaeological and off-site contexts. Just over half of the sites which have been investigated to date (Fig. 1), over 1200 locations, are archaeological contexts. The remainder are Quaternary geological contexts or off-site stratigraphic sequences. Sites examined range from the sub-Antarctic islands of South Georgia and the Falklands to the high Arctic of Greenland and Novaya Zemlya, from mummies in the deserts of Peru and Egypt to the wetlands and waterlogged deposits of urban centers in the British Isles and Canada (Buckland and Buckland 2006; Elias 2010). Insects may also occasionally be preserved by charring in, for example, burnt grain residues, or as impressions in pottery or daub. The application of paleoentomology to archaeology is sometimes referred to as archeoentomology. Site reconstructions are based on an interpretation of the environmental requirements of the species found in each sample, including a collation of their collective habitat data (or traits, see below) and an assessment of the importance of particular indicator species (such as pests or other specialists). The method relies on the concept of species constancy, both in terms of detailed morphology and of habitat. While there is some evidence for morphological change at the species level and probably more at the molecular one, recent work has shown that for some species at least the morphology holds as far back as 20 myr, the early Miocene (Fikáček et al. 2011). Similarly the origins of the tundra and mammoth steppe biomes, expanding at least once relatively rare montane habitats to continent-wide ones during the geologically relatively frequent Quaternary glaciations, provided opportunities which appear largely to have been exploited by shifting geographic range rather than species evolution. For example, the assemblages associated with the oldest Paleolithic material in the British Isles, from sites along the Norfolk coast, probably close to 1 million years old (Ashton 2017; Parfitt et al. 2010), are concordant with those from a modern Palearctic boreal forest. Thus, by identifying the taxa present in a sediment sample by comparison with modern reference material, a picture can be built up of the environment represented in the sediment catchment. In contrast, archaeological contexts may be dominated by insects accidentally incorporated from imported materials rather than those forming the autochthonous assemblage and may occasionally incorporate far-traveled hitchhikers on trade.

Sample size varies depending on the faunal group and context being studied. A single cubic centimeter of lake sediment will often provide an interpretable chironomid (non-biting midge) assemblage (e.g., Brooks 2003), while Quaternary and archaeological sediments for a more diverse range of insects usually rely upon a 5 L sample, although this may be far too large for contexts particularly rich in insect remains, such as wells and cesspits (e.g., Kenward et al. 1986; Buckland et al. 2016). Floor layers may be particularly difficult to interpret, and precise sampling and close integration with the other lines of evidence, particularly field archaeology, are essential, as well as, where possible, recourse to modern near-analogue situations in interpretation (e.g., Forbes et al. 2016). While it may be assumed that the insects represent the results of activities in the room, separation of autochthonous from allochthonous elements may be problematic. Large numbers of ectoparasites, for example, may reflect the traditional primate activity of delousing, or, if of sheep, they might point to wool processing (Buckland and Perry 1989). In house floor faunas, the buildup of twigs, hay, moss, and other materials, each with its characteristic fauna, used to make a habitable surface may also introduce large numbers of fly puparia (with several species of beetle) that are able to exploit the artificially warmed environments created by humans and their domestic stock beyond their natural range. Fecal and carrion communities may also develop in situ. Such often thermophilous faunas die out rapidly when a site is abandoned and are replaced as the "outside moves in" (Panagiotakopulu et al. 2007). To a lesser

Paleoentomology: Insects and Other Arthropods in Environmental Archaeology, Fig. 1 Map of the >1200 paleoentomological investigations currently stored in the BugsCEP database (Buckland and Buckland 2006) globally and in the database's core areas of Europe and the British Isles. Site symbols indicate the primary research context of the investigation, although some sites have multiple profiles. Note that a number of extra-European (mainly North American, Russian, and Australasian) investigations are not currently stored in the BugsCEP database and so not shown on this map (see Elias (2010a) for details)

extent, casual introductions into a room, for instance, species brought in as a result of human and other animal activities (e.g., in floor material, including fossil material in peat, in fodder, feces, foodstuffs, etc.), may form the more interesting elements in site interpretation, and room and area use may be evident in the distribution of faunas across floors. The interpretation of such layers is far from simple, and a perfect picture of room use should never be expected from the complex web of faunal movements (Fig. 2). Taphonomic processes, such as bioturbation, decay, mixing, and redeposition, can complicate the picture further, and it is essential to use multiple lines of proxy

Paleoentomology: Insects and Other Arthropods in Environmental Archaeology, Fig. 2 Insect evidence in a Norse Farm site. Arrows indicate potential movement of deposits containing insects or insect remains. (Modified from Buckland et al. 2004)

evidence, particularly plant macrofossil and sedimentological and other geoarchaeological analyses. While the same samples can be utilized to provide material for most of these, it is useful to have multiple samples both to examine within-context variation and to scan for additional identifiable fragments of rarer insect taxa; surplus material can always be disposed of at the end of a project, while resampling is usually impossible. Precision in sampling may also be problematic. The occasional visit of large herbivores to a waterhole may be evidenced by few dung beetles, and even the decay of large carrion provided by several enmired mammoths may be poorly resolved in the time-averaged samples from an adjacent stratigraphic sequence, even if well represented by the carrion flies in the nostrils (Erzinçlioğlu 2009). In the archaeological record, catastrophic events, from local fires to volcanic eruptions, may provide near instants-in-time but it is more usually difficult to link directly events with faunas. In the more successful multidisciplinary studies, the archeoentomologist has been directly associated with on-site sampling.

Historical Background

The development of both Quaternary entomology and archeoentomology owes much to techniques developed by the late Russell Coope and Peter Osborne at the University of Birmingham, UK, where in the late 1950s examination of samples from two Late Pleistocene sites in the English Midlands, Upton Warren and Chelford, indicated the potential of insect remains for reconstructing past climates and environments (Elias 2010a). This work was built upon that of Dane Kai Henriksen and the Swedish entomologist Carl Lindroth, although identification of insects from archaeological contexts had occasionally taken place over the previous century. The conviction that insects were a rapidly evolving group had led to the description of many new species from Quaternary fossil material, most of which, including that of W. D. Pierce on the Rancho La Brea material, has since been synonymized with extant taxa (Miller 1997). Coope's meticulous morphological work was initially met with skepticism in the entomological community, but Robert Angus'

careful comparison of preserved genital armatures of *Helophorus* with modern material convinced most of the massive range shifts occasioned by Quaternary climate change (cf. Angus 1973), a point finally driven home by the identification of one of the most frequent dung beetle fossils in the British last glacial as the Tibetan "endemic" *Aphodius holdereri* (Coope 1973). The rapidity of late Quaternary climate change apparent in insect faunas changing from arctic to warm temperate conditions in less than the sample resolution has taken longer to be appreciated, and it is only with the ice core data that the aphorism "don't touch that dial" has become widely accepted. The nuances of Holocene climate change, apparent in changing insect faunas, and its impact on human societies, however, are proving more difficult to dissect as the overriding influence on the insect fauna has become human activity.

Key Issues/Current Debates

Methodology

The technique of water sieving over 300 μm, followed by liquid paraffin (kerosene) flotation and sorting under a low-power binocular microscope, was summarized by Coope and Osborne (1968) in a paper on a Roman well, and this established the basic sample processing technique which has essentially remained unchanged to this day. Initially specimens were mounted on card slides with gum tragacanth with the more fragile material supported with a water soluble base, usually DMHF (dimethyl hydantoin formaldehyde) resin, but the sheer volume of material recovered meant that storage unmounted in alcohol has become more usual. Previous work relying on splitting samples along bedding planes or simple disaggregation in water resulted in a significant bias toward the larger taxa, although such material often resulted in the recovery of co-joined insect sclerites, considerably reducing the problems of identification, achieved by close comparison with identified modern material and occasional recourse to keys to the relevant group. This need for access to full reference collections – the UK beetle fauna alone has some 4000 species including incidentals (Duff 2018) – somewhat restricts the wider application of archeoentomology, and there are currently less than 30 active Quaternary entomologists globally, the majority of them based in Europe, although working internationally. Identifications are tabulated as minimum number of individuals (MNI), defined by the most numerous identified sclerite, usually heads, pronota (thoraces), and left or right elytron in terms of adult Coleoptera (beetles). Other groups may be represented by larval fragments, often identifiable to the species level in Trichoptera (caddis flies) or species group in Chironomidae (non-biting midges) and Simuliidae (blackfly), pupal fragments or puparia of Diptera (true flies), or occasionally near-complete individuals or other sclerites of Siphonaptera (fleas) and lice (Anoplura).

Since the earlier work on samples from archaeological contexts, particularly by Osborne, and later Girling, Kenward, and Robinson, perhaps the most significant advancements in archeoentomology have related to closer integration with modern entomological studies, partly stemming from a *caveat* issued by Kenward (1975) concerning the interpretation of urban assemblages. This relates largely to the different questions asked about natural and more strictly anthropogenic assemblages, where in the latter case the field archaeologist may want to know what has taken place on a particular spatiotemporal level, rather than the slightly more regional picture on a broader time plane which a sample from an adjacent peat bog might provide. Such questions usually require asking in the field at the point of sampling rather than post hoc. Attempts at habitat quantification, quantitative climate reconstruction (e.g., MCR – Atkinson et al. 1986), and taphonomic comparisons with modern pitfall and other assemblages (e.g., Smith 1999, 2000) have been integrated into freely available database software (Buckland and Buckland 2006; Buckland 2014). The advent of readily accessible computing power; cheap and user-friendly statistics software, for example, "Past" and "R"; and database management systems has provided the basis for a more complex and detailed handling of

the large amounts of numerical data which can be obtained from fossil and modern insect assemblages. It is not unusual, for example, for a single sample from a man-made pitfall, such as a well, to run to over a thousand individuals of over 200 taxa.

Sampling in the field is, as always, best undertaken by individuals trained either in environmental archaeology or Quaternary studies. The ability to identify, describe, and sample closed contexts is imperative if a reliable interpretation of a site is to be obtained, and while this might seem less of a problem with the more mechanical process of coring lakes and peat bogs, effective logging of stratigraphy in the field often precludes later problems of interpretation. This applies as much to natural contexts as archaeological ones, particularly where the pace of environmental or climate change is singularly rapid, as, for example, during the Lateglacial to Holocene transition, where transition from high arctic to warm temperate conditions takes place in less than a few decades and often defies the sampling interval. The ability of insect assemblages to describe phases of environmental change relies on samples representing as coherent a picture as possible, and large samples covering periods of rapid environmental change will inevitably produce diffuse and less-than-illustrative results. On archaeological sites, where possible, excavation by single context provides the greatest utility for taking samples and providing the entomological results which are most useful during interpretation, and the field archaeologist should be aware of the merits and limitations of the various palaeoecological techniques available. Unfortunately decisions are as likely to be based upon cost as utility – big machines and flashing lights after initial investment are cheaper than the long hours that the paleontologist has to spend at the microscope, and produce rapid if occasionally equivocal results.

Figure 3 shows how insect sample processing fits into the battery of biological proxy analysis methods typically used in archaeological investigations. After disaggregation in running water, followed by drainage of surplus water, liquid paraffin (called *kerosene* in North America, *Steinoliú* in Iceland, and *lysfotogen* in Sweden) is added to the sample retained on the sieve and the material floated with water. The sample is then left to settle for 15 min and the float poured off, a process which is repeated two further times with new water added. This floatation technique has been shown to preferentially concentrate insect remains over the plant and mineral matrix of a washed sample. A standard sieve size of 300 μm is used, although 150 μm may be required where the retrieval of particularly small sclerites, such as those of chironomid larval head capsules, which have a size range of <0.3 mm is intended; normally however, these would be recovered from separate subsamples of a few cubic centimeters. The float is washed in a mild detergent to remove the paraffin and then transferred to a beaker of either distilled water or 70–95% alcohol (Fig. 4). The latter has the advantage of reducing surface tension when sorting, but has disadvantages in terms of smell and evaporating more quickly. It should also be pointed out that paraffin flotation and alcohol storage should not be used if anything in the sample is to be used for radiocarbon dating (Panagiotakopulu et al. 2015). Insect sclerites are extracted into a tube of alcohol or distilled water using forceps, under a low-power binocular microscope. Long-term storage in ~75% ethanol or methanol is not advisable as it progressively results in bleaching and destruction of insect chitin and slightly acidified water may be preferable, although most previous material remains in the former medium, sometimes with glycerin added to reduce the risk of desiccation. Seeds, macroscopic charcoal, and other materials which may aid in interpretation are routinely extracted by most practitioners at this stage, although it should be noted that some seeds, such as those of *Juncus*, will pass through a 300 μm mesh, and the abundance of plant remains may necessitate subsampling. The non-floating residues should always be checked for heavier material such as artifacts, bones, or geologically interesting minerals which could aid interpretation.

Techniques using water and kerosene are not appropriate to the recovery of insect remains from desiccated sediments, where wetting is likely to destroy the remains, and gentle sieving with hand

Paleoentomology: Insects and Other Arthropods in Environmental Archaeology, Fig. 3 Paleoentomology is one of many biological proxy methods which can be used to investigate archaeological sites. Standard insect floatation method is illustrated but variations may be applied to cater for particular sediments or other requirements. (Modified from Buckland et al. 2004)

P

Paleoentomology: Insects and Other Arthropods in Environmental Archaeology, Fig. 4 Fossil insect material as part of a float. A binocular microscope and forceps are used to extract the identifiable insect remains from the matrix of amorphous plant materials. The sample comes from a Bronze Age dung pit at Pode Hole, Peterborough, UK, and the metallic black/blue fragments are the remains of dung beetles

picking out of larger debris may precede sorting under a binocular microscope. Put simply, dry material has to be kept dry, while wet can be wetted, but any change between states is likely to be deleterious. This leads to a number of long-term preservation problems. Dry material can be stored in closed glass or plastic tubes, which must be handled with care to avoid fragmentation.

Identification is undertaken by comparing the fossil parts (Fig. 5) with modern reference material (Fig. 6), illustrations, and photographs and through the use of identification keys for modern specimens or the occasionally surviving articulated fossil. It is often advantageous to group fossils by shape on a piece of filter paper, which should be kept damp at all times to prevent sclerites drying out and fracturing. The currently available identification keys are almost entirely based on characters rarely recovered in a fossil context, such as antennal segment lengths, tarsal structure, or genital armatures. The latter have major significance in some genera and have occurred in Quaternary sediments sufficiently frequently to form the basis of major biogeographic and taxonomic studies. Published keys are often more useful for confirming characteristics after identification than the actual process, although Lindroth, perhaps because of his interest in the Quaternary fossil record, often included comments on elytral microsculpture in his carabid keys (e.g., Lindroth 1986). Due to the vast diversity of insects, it is not uncommon for specialists in several groups to cooperate or send specimens to acknowledged experts in particular taxonomic groups.

The stages described above are undoubtedly the most time-consuming part of insect analyses; 5 L of poorly humified peat may take over a week to process, and samples from either remote islands or past and present arctic landscapes may be low in both diversity and numbers of individuals but nevertheless meriting detailed study. Interpretation of species lists relies on a detailed knowledge of general ecology and biology as well as the specifics of individual insect species ecology. Naturally, for archaeological contexts, it also requires an understanding of cultural activities relevant to the investigation, knowledge of the excavation in question, and also any particular questions that the excavator thinks might be answered by study of the insect remains. Here again it needs to be stressed that the best results are obtained by on-site collaboration between field archaeologist and all the relevant paleoecological specialists, something which is as yet unfortunately rarely achieved.

Insects in Archaeology

Although there were earlier studies, the first paper which effectively pointed out the potential of

Paleoentomology: Insects and Other Arthropods in Environmental Archaeology, Fig. 5 Fossil beetle parts (sclerites), primarily carabids (ground beetles), extracted and ready for identification. The sample is from a well excavated in Mårtensby, Vanda, Finland, and dendrochronologically dated to 1776/1777

Paleoentomology: Insects and Other Arthropods in Environmental Archaeology, Fig. 6 Reference collections consist of thousands of identified card or pin-mounted specimens. These collections take decades to establish and require curation and periodic treatment for pest infestations. Ironically enough, the pest species are common finds in archoentomology

insects in archaeology was that of Peter Osborne in 1971. Here, in a study of a refuse pit in the small town of Alcester in the English Midlands, he showed not only that the baggage of Roman occupation included an extended fauna of pests of stored products, grain weevils, and the saw-toothed grain beetle but also a longhorn beetle, *Trichoferus fasciculatus*, whose modern distribution suggests that it had arrived in an imported piece of woodwork, presumably furniture from the Mediterranean. Since Osborne's pioneer study, much work has gone into tracking the origins and movement of stored product pests and has included research ranging from the Neolithic and Bronze Age eastern Mediterranean (Panagiotakopulu and Buckland 2017) to post-medieval Québec (Bain et al. 2009). The results extend beyond archaeology. Until Coope and Osborne's find of the saw-toothed grain beetle, *Oryzaephilus surinamensis*, in the Romano-British Barnsley Park well, most entomologists would have regarded the species as a recent introduction from the New World, as the name given by Linnaeus, roughly translated as the rice lover from Surinam, would suggest. Other biogeographic conundra have also been elucidated from the archaeological fossil record. Fleas are not infrequent finds in archaeological contexts, and the origin of the so-called human flea, *Pulex irritans*, as an ectoparasite of a New World rodent, the guinea pig, has been considered (Buckland and Sadler 1989); its dispersal to Western Europe by the Neolithic was probably facilitated by small steps in the gift exchange of furs. This work has

more recently been followed up with DNA studies of fleas from South American mummies (Dittmar et al. 2003). Mummies have also frequently yielded head and body lice, and crab lice, *Pthirus pubis*, also reached the northern frontier of Rome (Kenward 1999), although its pre-Columbian occurrence in South America (Rick et al. 2002) suggests that, like the other human lice, it was an early uninvited guest.

In an early taphonomic study, Osborne (1983) showed that the pests of stored products passed virtually unaltered through the human digestive system when accidentally consumed as the nutty bits in bread made from whole-wheat flour or in porridge. This, as Kenward and Hall (1997, 2012) point out, equally applies to other omnivores and herbivores, and this has led to reinterpretation of some deposits, like the Roman sewer in York, where proximity of granaries is replaced by the more prosaic presence of feces. Other species in the sewer, however, cannot have been consumed, and the abundant small, stinging ant, *Hypoponera punctatissima*, therein again suggests an accidental import from warmer climes much further south, perhaps the Mediterranean (Buckland 1976). Similarly, first recorded in a Chinese tomb of 168 BC, the so-called rice weevil *Sitophilus oryzae* appears in late medieval deposits in Southampton (Grove 1995). Probably reaching the Mediterranean at least by the Roman period, the insects indicate trading connections which might otherwise be unnoticed, but further research on suitable deposits is needed. The equally misnamed *S. zeamais* has been found as impressions in early Neolithic Jomon pottery in Japan (Obata et al. 2011).

Moving away from the directly human, domestic animals may also be indicated by their ectoparasites. Dog, cat, and rat fleas are recorded from a number of sites; the more interesting of the last, *Xenopsylla cheopis*, the vector in bubonic plague, has yet to be found, although there has been interesting speculation on both the flea's and the epidemic's origins (Panagiotakopulu 2004). The ked, a wingless parasitic fly which lives on sheep and the fleece louse are not infrequent finds, although their presence is more likely to indicate wool processing than the animal itself. Its close relative, the deer ked, appears incidentally in the equipment of the late Neolithic "man in the ice" from the Italian Tirol (Gothe and Schöl 1994). There are a few records of goat and cattle lice, and it is worth noting that on sites with acidic sediments, such evidence from insect faunas may survive where animal bone does not. Buildings used to stall and stable animals may preserve other evidence than the rather infrequent ectoparasite in that fodder, litter, and manure have characteristic insect faunas. Stalling of cattle was deduced from the fly puparia associated with Neolithic structures in the Swiss Alps (Nielsen 1989), and there is similar evidence from southern Sweden at Alvastra. The characteristic assemblage of species associated with hay stored as fodder was exported with Norse settlers across the North Atlantic, although interpretation is complicated by the use of peat and turf both as animal litter and for sod walls, which introduce elements from the natural fauna (Fig. 2). The origins of this essentially anthropogenic assemblage have been considered by Kenward and Allison (1994). It extends into urban centers from the countryside, and much of the fauna was a feature of towns, before the demise of the horse as the main means of transport, the disappearance of the backyard pig, and the eclipse of meat supply on the hoof. A similar pattern of species emerges from sites as far apart as Novgorod, Oslo, York, and Dublin. To a certain extent, levels of hygiene can be deduced although there often remains the problem of strict contemporaneity with human occupation. Away from the cleaner areas of the fortress, for example, Roman York looks little different from Anglo-Scandinavian York (cf. Hall and Kenward 1990, 2004). In regions where urban origins go back much further, around the Mediterranean littoral or in the Near and Middle East, there is currently little evidence, and wells which would have acted as pitfalls for the local insect fauna would repay detailed study. The faunas from New Kingdom Amarna in Egypt, preserved by desiccation in deposits between house floors and in a pig pen, hint at conditions not too different from those of peri-urban and rural housing in the Middle East at the present day, with a mix of pests of stored products, probably derived from animal dung, ectoparasites, including bed bugs and flies, and fodder feeders (Panagiotakopulu and Buckland 2010).

While the immediate environment, reconstructed from insect remains, is perhaps of most significance

to the field archaeologist, the regional picture which the insect evidence presents provides detail which is largely unavailable from other sources. Pollen may be interpreted in terms of forest composition in the broadest sense, although the extent of clearings, both natural and anthropogenic in the woodland, is often difficult to see. The insect fossil record for the early to mid-Holocene shows that after initial rapid warming to conditions slightly warmer, or at least more continental than present day, the development of closed forest was fairly rapid, if initially out of step with amelioration – it took time for the trees to catch up and beetles associated with decaying wood and its fungi appear long before their more usual hosts (e.g., Osborne 1974), a feature of the fact that it is often the situation and state of decay which is more important to the insect than the tree species. A similar pattern is evident in the herbivore dung faunas, where situation or substrate is more important than species of origin. There are, however, among the deadwood fauna elements, such as many scolytids, bark beetles, which are more host specific and could have profound impact upon forest composition in both the Old and New Worlds. More has perhaps been written on *Scolytus scolytus*, the elm bark beetle, than any other insect in archaeology (e.g., Clark and Edwards 2004), and its occurrence has been linked with the widespread decline in elm which heralds the Neolithic. Whether human impact is needed is debatable, although increased stress on the forest as a result of domestic grazing pressure at a time of climate stress might be relevant. It is worth noting, however, that a catastrophic mid-Holocene decline in hemlock in North America has been similarly linked to an insect-borne pathogen (Bhiry and Filion 1996). Whatever the cause, from the elm decline onward, forest faunas come under increasing pressure as human impact increases. Of the regional extirpations of species, most easily seen in the offshore island of Britain, roughly 80% of the losses relate directly to the forest and much of the remainder has some association with woodland (Kenward and Whitehouse 2010). As woodland faunas decline, dung faunas increase, and species which are rare in the mid-Holocene become increasingly common; others are fresh introductions, some not seen since the more open landscape of the previous, slightly warmer interglacial, which with elephants, rhinoceros, and hippopotami was curiously lacking in humans in northern Europe. The extinction of the larger herbivores at the end of the last Glaciation had a significant impact on the natural dung fauna, just as the disappearance of mammoth and wooly rhinoceros had on the colder fauna. While the frequent dung beetle in the middle of the last glaciation, *Aphodius holdereri*, found a refuge in yak dung on the high Tibetan Plateau (Coope 1973), the one certain extinction from the Palearctic insect fauna is a botfly, *Coboldia rusanovae*, which was parasitic on mammoths (Grunin 1973).

Quantitative Environmental Reconstruction and Species Habitat Traits

Paleoentomology, as archeobotany, has traditionally relied on qualitative or semi-quantitative analysis of taxa. Indicator species and the subjective expert assessment of the relative ecological implications of taxa have led interpretation, based on extensive knowledge of the relevant entomological sources. This is most likely a result of several factors, including a past lack of easily accessible computing power, an absence of relevant databases, the prevalence of small numbers of fossils in samples, and certain skepticism over the application of techniques from ecology to the inevitably more fragmentary fossil record. The subject has therefore lagged behind palynology in this respect, which has had an active quantification community for many years, even if a considerable body of practitioners prefers to use simple, and often misleading, percentage-based analyses.

A fossil insect assemblage retrieved from a sediment sample is in itself a sample of the population of the environment at the time of deposition. This is the case for any type of deposit, be it archaeological context or lake sediment, and there is significant overlap with forensic entomology and the deposits of a crime scene (cf. Panagiotakopulu and Buckland 2012; Erzinçlioğlu 2009; Smith 1986). By the time a species list has been obtained, however, the sample has been subjected to a number of taphonomic processes which will have reduced its ability to represent fully that insect population. The representivity of the sample, and the resulting interpretation, depends on a number of factors, which collectively come under the banner of taphonomy.

A number of studies have investigated sample representivity at both the individual species and assemblage/community level, and Kenward in particular (e.g., Carrott and Kenward 2001) has looked at the concept of a "death assemblage" in comparison with living populations in environments useful to archaeology. The potential non-analogue problem, where a fossil assemblage has no modern equivalent (see below), is more easily avoided when the ecology of each individual species is treated on its own merit, rather than assuming that the relationships between a *group* of species and a particular habitat are constant.

Although the ecology of insects is complex, the habitat preferences of most species of insect can be summarized in terms of a restricted set of general or specific "traits." In their most reduced form, these may simply be "terrestrial" or "aquatic", or in the archaeological context, "indoor" or "outdoor," but more nuanced terms, including a number of specific indicator groups such as parasites and obligate dung indicators, are more useful for the interpretation of culturally affected deposits and when describing landscape change. Klaus Koch (1989–1992) devised a set of over 120 categories to describe the ecology, habitat, and feeding habits (traits) of thousands of beetle species, although this system is perhaps too comprehensive to allow for an easily understandable overview of environmental change, or the differences between samples, at a site. The BugsCEP software (Buckland and Buckland 2006) implemented a set of 22 traits, based on those of Koch and Robinson (1983), in order to provide for a more manageable, yet useful and reproducible, quantification of the environmental implications of the species found in samples. Quantitative environmental reconstruction can be undertaken by simply tallying the number of species or individuals falling into each category. The results can then be standardized by dividing the numbers for each category and sample by the sum for all categories for each sample, and easily visualized as a bar chart (Fig. 7). Standardization allows for the inter-comparison of results between samples and sites irrespective of variations in sample size (both in terms of volume and biodiversity).

There are, of course, numerous problems with reducing the implications of a set of complex organisms to 22 bar charts, and users of any classification system must be aware of the importance of understanding insect ecology and potential variation in the implications of the categories. Halotolerant species, for example, may either indicate a coastal location, inland saline groundwaters, *or* the plowing up of mineral salts in an arable field of newly exposed raw soils in arctic landscapes. In the context of more immediate archaeological interpretation, buried corpse faunas provide an instructive example. Dominated by beetle predators on maggots, they can show overlap with similarly foul assemblages from other urban contexts, such as cesspits, and the taphonomy may reduce the essential prey, largely phorid fly larvae, to the unidentifiable. Again, the importance of provision of all relevant archaeological information to the specialist is evident. Trait-based reconstruction should always be a tool in the interpretation process and not an end in itself.

Contemporary Biodiversity and Fossil Data Interpretation

As insects are present in every terrestrial and freshwater environment, and many species are highly specialized in their ecological preferences, knowledge of arthropod ecology is essential when reconstructing past environments, climates, and human activities. Disturbances as a result of human activity can be reflected in the degree of openness and structure of woodlands and in turn may reflect the impact of grazing and land management practices, as well as more immediate on-site impacts. Work on modern analogues aims toward understanding how well insect assemblages characterize the surrounding environment, and work has focused on studying how well insects reflect forest structure and landscape openness (e.g., Buckland et al. 2005; Smith et al. 2010). Beetle and true bugs (Coleoptera and Hemiptera) assemblages have been studied from a wide range of modern deposits with varying spatial relationships with respect to woodland and trees. Results indicate that a significant proportion of tree-associated beetles and bugs are to be expected within a woodland area, and that the abundance of tree-associated species will indeed

Paleoentomology: Insects and Other Arthropods in Environmental Archaeology, Fig. 7 Habitat diagrams created from results produced using the BugStats tool in the BugsCEP software (see Buckland (2007) for details), showing a sequence of samples taken from an eleventh-century ditch on the border of a deer park at Conisbrough, UK. The upper diagram (**a**) shows bars which are proportional to the number of individuals found in each sample, for each habitat class/trait. The lower diagram (**b**) shows these values standardized by the total number of traits in each sample (a taxon may occur in more than one category, i.e., have more than one trait). Three of the 22 habitats have been omitted for clarity. The chart furthest to the right in each diagram shows the total number of individuals and taxa in each sample. Note that in (**a**), the individual habitat charts more or less mirror the number of individuals per sample chart, making it difficult to understand the relative importance of each habitat between samples. Standardization of these values in (**b**) negates the effect of differing sample richness and biodiversity, allowing us to see that, with the exception of s4052, the samples indicate similar conditions of deciduous trees overhanging a muddy ditch, with decaying vegetative and animal remains nearby. In the background, pasture and meadows are present

rapidly reduce with distance from woodland (Kenward 2006). Similar results are shown in studies in Finland on ground beetles (Carabidae) from pitfall traps along transects running from within a forested area to within open farmland. These concluded that forest ground beetles were abundant within the forest and right up to the forest edge, whereas the number of open-habitat species decreased drastically 5–10 m into the forest edge (Koivula et al. 2004). Buckland (2007) compared the Finnish results using the environmental reconstruction facilities of the BugsCEP software (see below), demonstrating that the latter could be used as a tool for studying modern insect assemblages and environments in order to validate paleoentomological studies and Quaternary environmental reconstructions. When using arthropods to reconstruct the local environment, or the on-site conditions, it is important to understand the spatial representivity of the samples. This is especially important when sampling in natural contexts, or wells/refuse pits which act as pitfall traps, where many of the taxa found are often of natural (non-synanthropic) origin. Smith et al. (2010) examined the degree to which tree-associated beetles and pollen could be used to predict openness in woodland. They suggest that it is possible to use tree-associated beetles to assess the degree of local vegetation openness and the relative intensity of land use by grazing animals within a limited area, roughly within 100–200 m radius of the sampling site. A similar modern study on dung faunas (Smith et al. 2014) was less successful, although this may reflect the limited time window of sampling and the distance between sampling sites.

It is difficult to replicate the taphonomic pathways of fossil assemblages by sampling strategies for modern insect communities, although pitfall trap collections from traditionally managed farms show many similarities with fossil faunas from wells. In terms of species there have been significant recent changes, which make well assemblages from Roman sites more akin to collections made in the early nineteenth century than to those made in the late twentieth, by which time mechanization, herbicides, insecticides, helminthicides, and plowing up of old pasture had driven many close to at least local extinction; the process continues in the present century. Similar *caveat*s apply to woodland assemblages and the medieval town has, perhaps fortunately, no modern analogues. It is unfortunate that earlier studies of insect faunas are rarely quantified beyond a broad very common, common, uncommon, rare, and very rare framework, and more studies are needed, collecting insects with an aim toward improving the interpretation of fossil assemblages. Unfortunately the majority of biodiversity surveys concentrate on specific groups (such as ground beetles or forestry pests), rather than the complete fauna in any location.

Climate Change Studies

Fossil beetles were among the first proxies used to identify the rapid nature of global warming at the end of the last Ice Age, later confirmed by ice core data. The most established methods for climate reconstruction from fossil beetles is the mutual climatic range method (MCR) (cf. Atkinson et al. 1986), available with slight modification in the BugsCEP software (Buckland 2007). MCR is a mathematically simple modern analogue technique, whereby the climate, although not necessarily the geographic locality, in which the majority of the species in a sample live today, is considered the most probable climate represented by the fossils found together in a sample (see Elias 2010a for methodology). Unlike assemblage-based methods, and in common with the trait-based approach described above, MCR does not assume species communities and independently evaluates each species, providing a climatic rather than geographic envelope and then integrating the whole to provide a most probable regime. It therefore avoids issues of non-analogue communities when reconstructing the climates of periods where community structures may have been different from any of those observable today, such as the mammoth steppe which is considered to have covered much of what are now northern temperate regions during the last glaciation (Zimov et al. 2012).

The current MCR calibration dataset includes the temperature requirements of 436 beetle species known fossil from northern Europe, based on several thousand point source and area distribution maps. There is therefore considerable room

for expansion, especially taxa from more continental climates and Mediterranean regions. Beetle MCR results have been shown to slightly underestimate extreme climates, and this may be a reflection of the limits of the calibration data. Updated software utilizing a combination of online biodiversity data collated from museum collections (e.g., GBIF, www.gbif.org) with careful manual quality control of the data will help improve the relevance and accuracy of future MCR calculations, although many data require checking and much remains to be culled from under-researched museum collections.

There are a number of other insect orientated climate reconstruction methods in use, and chironomid-based reconstructions have been used extensively (e.g., Brooks et al. 2012). A number of alternatives to MCR for beetles have also been investigated and the reader is directed toward Elias (2010a) for an overview.

BugsCEP Database and Software

The Bugs Coleopteran Ecology Package (BugsCEP; http://www.bugscep.com; Buckland and Buckland 2006) is currently the only freely available database for fossil and modern insect data (although there are plans to make the same data available online through the SEAD, http://www.sead.se, and Neotoma, http://www.neotomadb.org, research data infrastructures). BugsCEP stores published raw data on the occurrence and abundance of individual taxa, as well as accompanying dating evidence and bibliographic and other site metadata. The system also provides an extensive habitat and geographic database for most taxa, along with software tools for entering new data, analysis, aiding interpretation, and the identification of similar sites. Table 1 summarizes the contents of the database at the time of writing (August 2017). The database is considered as reasonably complete in terms of the published European fossil record, including a large amount of gray literature in unpublished archaeological reports. A large amount of data from studies in Russia are contained in the database of Siberian fossil insects (QUINSIB; Kuzmina 2014), which has yet to be made publicly available (although excerpts are available on request). Further data from North America is currently being ingested into the Neotoma Paleoecology Database (http://neotoma.org), and the merger of these databases would represent a considerable step toward providing a more integrated Holarctic perspective on insect biogeography.

In addition to data browsers and retrieval tools, BugsCEP provides a number of software tools, as the most important of which are outlined in Table 2. These are designed to help in the interpretation of archaeological and natural environments and reduce the time and expertise required for a number of common data-intensive exercises, such as compiling a list of habitat descriptions and references associated with the species found at a site or a bar chart of species habitat traits through a series of samples (Fig. 7).

Future Directions

Paleoentomology can provide an enormous amount of detailed information with regard to past human and natural environments, and it is hoped that its use will only increase in the future as more archaeologists realize this fact. User-friendly database software, online portals, and GIS technology will enable the volume and scope of the all-important reference data to be expanded, also increasing the relevance and applicability of insect data, although access to and maintenance of reference collections will remain a problem. Habitat summary data, modern environment calibration data, and MCR climate reference data are areas which could be expanded upon relatively easily, although the gathering of species collection data is time consuming and difficult to source funding for. The paleoentomological community is, however, small and therefore of limited productivity even if the individuals themselves are not. Increased student recruitment is therefore essential, especially at the postgraduate level, if the community is to grow, and it is hoped that the integration and community-based growth of digital tools will help toward encouraging more students to continue to higher levels.

DNA-based studies, while no replacement for morphology-based identifications (e.g., Will and

Paleoentomology: Insects and Other Arthropods in Environmental Archaeology, Table 1 Enumeration of the BugsCEP database (as of 10 August 2017), illustrating the nature and extent of the (primarily European) Quaternary fossil insect record. The database is being continually updated, and these figures are thus out of date. Refer to the current version of the database or its website for current information (www.bugscep.com)

Species related	
11,123	Taxa with 6,748 synonyms
932	Species association records (e.g., predator on, predated by, etc.)
1,934	UK Red Data Book rarity records (RDB)
11,770	Size attributes (mainly minimum and maximum sizes)
428	Identification keys to families, genera, and species largely by Peter Skidmore, with some translations into English of French and German sources
Fossil record	
1,283	Sites (geographical locations which may include multiple excavations and datasets)
1,422	Abundance datasets, of which 713 are archaeological and 620 stratigraphic sequences
189,704	Fossil or modern record entries (finds of a particular taxa at a particular site), including 715,261 individual taxon identifications (occurrences)
1,961	Calendar-based dates – specific years or ranges of calendar years Ranging from present day to dendrochronological dates >5,000 BC
7,471	Period date records – encompassing period types from archaeological to vegetation and geological; ranging from Pleistocene to Modern, and used where no more specific data are available
1,315	Radiometric dates – mainly radiocarbon but also Uranium series, OSL, etc. ranging from 370 to 167,500 BP
Bibliography	
5,965	References, of which 11,360 are the dataset sources
Ecology and climate reference data	
436	MCR species thermal envelopes (see "Climate Change Studies")
34,863	Habitat and ecology text abstracts Text concerning the habitat and ecology of a species as described by the cited author
37,955	Distribution text abstracts
	Distribution notes for a species from a cited author
8,997	Bugs ecology code (habitat trait) assignments – classification of species according to a limited set of general habitats and used for rapid environmental reconstruction (see "Quantitative Environmental Reconstruction and Species Habitat Traits")
17,032	Koch ecology code (habitat trait) assignments – classification of species according to an extensive set of habitat and ecology descriptions, based on Koch (1989–1992) with translation and additions (see "Quantitative Environmental Reconstruction and Species Habitat Traits")
9,893	UK adult activity month records

Rubinoff 2004), when used in combination with the methods described above, are likely to play an important role in studying long-term changes in biogeography (cf. Dittmar et al. 2003). In particular, issues of faunal origins and the movement of pest species (cf. Panagiotakopulu and Buckland 2017) are likely to benefit from the molecular approach, especially with its ability to identify genetically similar populations. Fossils and museum specimens of parasitic insects may also prove useful as information stores for the DNA of parasites and pathogens and thus advance the understanding of the spread of insect-borne diseases and past epidemics.

Although all proxy data sources can provide useful information, it has been suggested that the limits of single proxy reconstructions are being reached, and that we gain less and less from each new investigation. If this is true, then multi-proxy integration is the way forward. With the databases now available for several proxies, and an increasing number of multi-proxy databases under construction, there is much scope for integrated environmental and climate reconstructions where the limits of one proxy may be strengthened by the advantages of another. A logical continuation of this would be the integration with an increasingly accessible range of external data sources for

Paleoentomology: Insects and Other Arthropods in Environmental Archaeology, Table 2 The main tools provided by the BugsCEP software interface deliver the results of complex queries at the click of a mouse, reducing the need for complex query construction in database management software

Tool	Form, purpose and results
Modern habitat and distribution data collation	For any dataset, the fully referenced habitat and broad modern distribution data for each species found can be extracted. This potentially saves hours of literature searching and, along with the environmental and climate reconstructions, provides the foundations for site interpretation
Climate reconstruction	The BugsMCR tool uses the MCR dataset (see "Climate Change Studies") to calculate the most probable thermal regimes represented by the species found in each sample at a site. Jackknifing may be applied to give an indication of the reliability of reconstructions, which generally are related to the number of species in the sample or its temporal resolution. The system can also be used to visualize the species thermal envelopes for any dataset as well as predict which other species could survive in the temperature range tolerated by any single species (see Vickers and Buckland 2015)
Habitat trait based on environmental reconstruction and statistics	The BugStats tool uses the Bugs ecology code system to quantitatively summarize the habitats represented by each sample at a site. The results can be expressed as bar charts (Fig. 7) or a text report, and a variety of pretreatment and standardizations can be applied to improve inter-sample comparability and aid interpretation. Correlation matrices may also be produced comparing the similarity of the assemblage of each sample with every other sample at a site
Search by habitat, distribution, and rarity	The database can be queried for a list of species preferring any single or combination of habitat traits from the BugsCEP or Koch systems or where any specified word is included in their habitat or distribution data. The UK RDB data (see Table 1) may also be queried in the same session and logical operators (AND, OR, NOT) are catered for. Results may be output as species lists or a list of sites containing the species retrieved

ecology, biodiversity, and also ethnography and cultural history. Such inter-archive linking could greatly improve the speed with which basic quantifications and interpretations could be processed and thus leave more time for the more detailed qualitative interpretation of results and their implications.

Paleoethnobotany

Glenn S. L. Stuart
Department of Archaeology and Anthropology, University of Saskatchewan, Saskatoon, SK, Canada

Introduction and Definition

From our earliest ancestors through to modern societies, plants have always been of importance to people. They were and remain a crucial element of people's diet, whether their subsistence strategies centered on hunting and gathering or agriculture. Plants also provided fuel, were the basis for most medicines, formed the source of many tools, and were instrumental in building shelter. Further, they were used in a wide range of ceremonies, illustrated in artwork, discussed in early writings, and helped identify and demarcate places of economic and spiritual importance. In short, with few exceptions, they were of fundamental significance to past peoples around the globe.

The study of the interaction and interrelationships between plants and past peoples falls within the realm of paleoethnobotany. More specifically, paleoethnobotany is the study of behavioral and ecological interactions between past peoples and plants, documented through the analysis of plant remains recovered from archaeological sites (Ford 1979; Pearsall 2015). It uses an archaeological and ecological approach to elucidate the nature of human–plant interaction, seeking to understand not only which plants were used in construction and manufacturing, as food or fuel, in religious observation, or as medicines, but how they were used and why some plants had such uses while others did not.

Paleoethnobotany is not about simply cataloguing which plants past peoples used, but rather attempts to better understand the nature of plant–human interdependency. Its scope of investigation ranges dramatically, from, for example, exploring the variety of plant taxa present in an archaeological site and discussing their potential uses, to describing how season of availability of particular resources may have structured past settlement patterns and subsistence practices, to documenting hunter-and-gatherer niche construction, to tracing the transition to food production and the origins of cultivated plants, and to chronicling human construction and management of agricultural landscapes (Pearsall 2015).

To accomplish such research, paleoethnobotany combines two distinct research venues, plant science and archaeology. That the materials of study – plant remains – are recovered from archaeological sites makes paleoethnobotany an essentially archaeological approach. Yet the presence of such remains in a site may or may not

derive directly from human activities. Seeds and pollen recovered from an archaeological site, for example, may relate directly to resource use or may be part of the natural seed or pollen "rain" (Minnis 1981). Recovery of plant materials such as charcoal or charred seeds directly from archaeological features, or starch off of artifacts themselves, often clarifies the relationship, but so too does an understanding of the plant's ecology and resource potential. A paleoethnobotanist, therefore, needs to be able to identify recovered plant remains, understand the ecology of such plants, and recognize their human resource potential.

Plant materials that can be linked to human activity speak directly to the question of plant – human interaction, but plant remains that are "naturally" deposited within an archaeological site also may provide information in regard to the nature of human – plant interrelationships. The recovery of microscopic particles like pollen or phytoliths, particularly in nonfeature contexts, may not be the direct result of human manipulation and use of plants, but their deposition often arises indirectly as a result of human activity and environmental interaction. Land clearance activities associated with agricultural or other activities, for example, will often have a dramatic impact on the "natural" pollen rain. Finally, even in those cases where recovered remains are demonstrably not the product of either direct or indirect human activity, they still provide information in regard to past environmental conditions, and therefore the environmental circumstances under which past peoples lived and adapted.

Plant remains recovered from archaeological sites are also sometimes referred to as archaeobotanical remains, and the study of the archaeobotanical record as archaeobotany. While in practice the terms paleoethnobotany and archaeobotany are often used interchangeably – with North American authors tending to prefer the former and European researchers the latter – separating them can have utility. Ford (1979: 299) noted that the analysis of plant remains from archaeological sites was (and is) useful not only in regard to human–plant interaction, but also toward "problems unrelated to human activities." From this perspective, then, botanical remains recovered from archaeological sites may be used to reconstruct paleobotanical patterns, biological evolution, and paleoecology, to name a few, in addition to human–plant interaction. Thus, Ford (1979: 299) defined archaeobotany "as the study of plant remains from archaeological sites," indicating that it "refers to the *recovery* and *identification* of plants by specialists regardless of discipline," whereas "paleoethnobotany implies their *interpretation* by particular specialists" (emphases in original). The advantage of such a distinction is that it broadens the research potential of plant remains from archaeological sites, rather than simply precluding that such remains are only suitable for providing information on human activities. Paleoethnobotany, then, in relating specifically to the interaction between people and plants, becomes a subdiscipline within archaeobotany. It is important to note, however, that not all or even most researchers make this distinction.

Conversely, the analysis of plant remains from nonarchaeological contexts – the more typical source of paleobotanical and paleoecological data – can be of fundamental importance in addressing past human activity. Analyses of paleobotanical remains allow documentation of diachronic and synchronic environmental variability and how such variability may have affected past subsistence and settlement systems. Such data also provide a baseline (or control) from which to identify behaviorally induced botanical patterns. For example, pollen, phytolith, and microcharcoal derived from lacustrine cores has commonly been used to help address issues relating to human environmental impact and niche construction (e.g., Magyari et al. 2012). Such research is often thought of as paleoethnobotanical, even though the data are not derived from archaeological sites (Pearsall 2015).

Paleoethnobotany is not necessarily just about plant–human interaction, however. Chronology, for example, is generally of considerable archaeological concern. Paleoethnobotanical research can be instrumental in not only identifying those contexts most suitable for chronometric analysis, but will also provide the most appropriate samples. Rather than use of wood for radiometric dating, with its well-documented limitations, the

routine separation, identification, and tabulation of charred annuals provides the ideal specimens for radiocarbon assays. Furthermore, pollen can be radiometrically dated, and pollen analysis would identify those samples, such as ones containing high concentrations of economic plants, most appropriate for dating.

Still, most paleoethnobotanical research tends to revolve around subsistence and settlement. Here, analyses of paleoethnobotanical remains can be expected to identify patterns of utilization and help determine relative emphasis on different subsistence strategies. The relative proportion of remains of domesticates and cultivated plants versus wild and collected plants, for example, allows the paleoethnobotanist to assess the relative importance of cultivated versus collected foods at any given site, and how these reliances differ spatially and temporally. The relative abundance of such plant remains can also inform on occupational intensity. Yet it is nevertheless important to point out that even if the main focus of a given study is on subsistence the differential distribution of floral (and faunal) remains within a site may reveal data on specialized activity loci, functional variability, social hierarchy, or other factors. Further, identification of relationships between artifact types (e.g., spindle whorls) and plant resources (e.g., cotton or agave fibers) can be used to infer local production. And correlation of distribution patterns of botanical remains with those of faunal remains, stone tools, and vessel forms can be used to establish site/feature function. Thus, even if a project is designed specifically toward addressing subsistence, the data obtained can still be used to pursue topics beyond those originally conceived.

While such basic questions in regard to diet and plant use are still of importance, paleoethnobotany has also moved into discussions of status, ethnicity, chronological thresholds, cultural evolution, politics, and ideology, and it has played a prominent role in documenting just how artificial the conceptual divide between hunter-and-gatherers and agriculturalists really is. It also has played a key role in discussion of human environmental impact and adaptation to changing climates.

In her 1999 summary article *Recent Research in Paleoethnobotany*, Christine Hastorf noted almost 20 years ago that there are few if any archaeological questions to which paleoethnobotany cannot make a contribution. This has not changed; indeed, as the scope and complexity of paleoethnobotanical research has increased, so too has its potential.

Historical Background

Scientific research of plant remains from archaeological sites began long before the discipline of paleoethnobotany was defined. Perhaps the first example derives from Egypt with Giuseppe (Joseph) Passalacqua, who lead an excavation of ancient tombs at Dier el-Bahri on the west bank of the Nile, opposite Thebes (Luxor). Among the artifacts he found dried plant remains, which he turned over to botanist C. Kunth, who reported the results of his analysis in Passalacqua's 1826 report. Some decades later but still within the infancy of what we would now call paleoethnobotanical analysis is the work of botanist Oswald Heer, who analyzed waterlogged plant remains from prehistoric village sites in Switzerland in 1866, discovering a range of grains, legumes, fruits and berries, nuts, and various other plant parts. Once pioneers like Kunth and Heer had documented that plant remains could survive in archaeological sites, studies continued in Egypt and at the Swiss lakes, but also expanded into Central Europe, Germany, Italy, Greece, and Anatolia. Most of these studies consisted of taxonomic lists and descriptions of species present at a site, though a few researchers used archaeological materials to study the evolutionary history of particular taxa (Renfrew 1973).

Paleoethnobotany as a discipline derives from ethnobotany which, in general, refers to the scientific study and recording of the interrelationships between plants and people, particularly from the perspective of traditional knowledge of local or indigenous cultures. Stephen Powers can be seen as the grandfather of the discipline publishing, in 1875, an article entitled *Aboriginal Botany*, which he defined as "all the forms of the vegetable

world which the aborigines use for medicine, food, textile fabrics, ornaments, etc." But the term ethnobotany itself did not appear for another two decades, when John Harshberger used it in a lecture he delivered in Pennsylvania in 1895. His subsequent publication, *The Purposes of Ethnobotany* – which, intriguingly, had as its impetus the recovery of (what we would now term) paleoethnobotanical items from Mancos Cañon in Colorado – can be argued to have inaugurated the field of study.

In this and other works, Harshberger emphasized how people *used* plants. As research continued, however, ethnobotany began to move beyond a primary association with plant use to developing a better understanding of the multiple aspects of human plant interaction. Volney Jones, of the Ethnobotanical Laboratory of the University of Michigan Museum of Anthropology, championed this perspective, stating "that ethnobotany should be concerned not only with the uses of plants, but with the entire range of relations between primitive man and plants" (Jones 1941: 219).

In this emphasis on ethnobotany as the study of the interrelations of aboriginal peoples and plants, Volney Jones (1941: 220) specifically noted the bond between plant sciences and anthropology, as ethnobotany drew upon both for "its approach, methods, and data." Jones saw ethnobotanists as working between the fields of anthropology and botany, and therefore presenting data, results, and interpretations of interest to anthropologists, plant scientists, or both. Following Harshberger, he also specifically included the study of plants from archaeological sites within the rubric of ethnobotany, noting that cooperation between archaeologists and botanists had been leading to new discoveries of interest to both. While seeing value in botanists cooperating with archaeologists and anthropologists, he (Jones 1941: 220) also clearly believed that to maximize its research potential, ethnobotanical work would best be accomplished by researchers familiar with the "techniques, methods and approach" of both anthropology and plant science, in other words, dedicated specialists. Problematic to him (Jones 1941: 220) was the fact that "few individuals have given sustained attention to investigations in ethnobotany for its own sake" with much of the research being done as ancillary work to other pursuits within the fields of anthropology, archaeology, and botany, as well as agriculture, history, folklore, medicine, pharmacy, and others.

In addition to being one of the first to call for this more fully interdisciplinary approach, Jones was also among the first to note the ecological relationship between people and plants, a characterization that continues to hold for modern ethnobotanical and paleoethnobotanical research. Thus, Volney Jones can be seen as having substantially influenced the field of ethnobotanical investigation, steering it toward the course it follows today. It is not surprising, therefore, that he has been described as the father of paleoethnobotany (Pearsall 2015: 27).

Ethnobotany and paleoethnobotany originated with the analysis of macrobotanical remains – plant remains large enough to be seen with the naked eye. But around the same time as Jones was calling for more comprehensive ethnobotanical research, pollen research began to be incorporated into archaeological research. Fossil pollen data were used to date the beginnings of the Neolithic period in Denmark, for example, based on the decline of elm (*Ulmus*) pollen, an increase in weedy plants argued to be associated with human environmental disturbance, and the presence of pollen from domesticated plants (cereals).

Paleoethnobotany's emphasis on agriculture was also seen through research locations, with a particular emphasis on the Near East beginning in the 1950s. These studies emphasized the evolution and domestication of major food plants, like wheat, rye, and barley. The most prolific researcher in this regard was probably Danish botanist Hans Helbaek, who not only worked with various leading scholars of the area (Robert Braidwood, Frank Hole, Kent Flannery, and James Mellaart) and published numerous articles and reports on the Near East, but also conducted several studies in Europe. This interest, and emphasis, on the origins and spread of agriculture, employing both macrobotanical and pollen data, has continued through the years and remains an important topic today (Langlie et al. 2014; Magyari et al. 2012).

Though much research that we would call paleoethnobotany was occurring, the term itself was not introduced until 1959, when Hans Helbaek employed it within the context of his research on Old World domestication, including referring to himself as a paleoethnobotanist. Reflecting upon Heer's influence on the development of the analysis of archaeological plant remains, Helbaek refers to Heer as the first paleoethnobotanist (Helbaek 1959). Similar to Jones, Helbaek wrote that paleoethnobotany resulted from the joining of botany and archaeology, but he placed the emphasis on the latter, stating "it is clear that any domesticated plant is an artifact, a product of human manipulation" (Helbaek 1959: 365). Renfrew (1973: 1) took a similar position, defining the discipline "...as the study of the remains of plants cultivated or utilized by man in ancient times, which have survived in archaeological contexts." Like Helbaek, and contra Jones, Renfrew's definition emphasized the archaeological (anthropological) side, placing less emphasis on ecology. Shortly thereafter, however, Richard Ford (1979: 286) defined paleoethnobotany as "the analysis and interpretation of the *direct* interrelationships between humans and plants for whatever purpose as manifested in the archaeological record" (emphasis in original), thus reaffirming the joint ecological and anthropological components previously articulated by Jones.

Around this same time, the International Work Group for Paleoethnobotany (IWGP) was established. The IWGP brought together a group of European and Mid-Eastern paleoethnobotanists at Kacina Castle in Prague in 1968 to share their research and encourage contacts amongst members of what was then a growing but still fairly small group. These meetings have continued at 3-year intervals, and like the discipline itself the IWGP has grown, with the 2016 meeting in Paris having over 100 presentations and about 250 attendees from around 35 countries. Publication of proceedings volumes and bibliographies from these meetings has proven to be of great value to paleoethnobotanists and other interested parties. While the emphasis of the IWGP has remained on the Old World, the Group is not exclusive to the Old World and contributions from the New World have been welcomed.

Research – and the number of researchers – in the New World trailed that of the Near East and Europe, with much of the early work being conducting by European researchers. The earliest such example shortly postdates the beginning of Heer's work in Switzerland and involved the examination of a Peruvian mummy bundle. This was soon followed by an accounting of plant specimens from Ancon and other locations in Peru. Though Europeans and Latin American scholars continued to work in Peru, there was relatively little paleoethnobotanical research conducted elsewhere until after 1900.

The few paleoethnobotanical studies that were conducted outside of Peru were written mainly by botanists, whose interests lay in natural rather than cultural history. With the rise of anthropology and the training of ethnologists in the 1900s, however, research perspectives began to change. The focus of these anthropologists and ethnologists was on the Native American perspective and how plants were integrated into their world. David P. Barrows' 1897 dissertation *The Ethnobotany of Coahuila Indians of Southern California* (University of Chicago) exemplified this approach, stressing the social and religious importance of plants. One of the more intriguing studies was Col. Bennet Young's 1910 publication *The Prehistoric Men of Kentucky* which describes plant materials in human coprolites (fossilized feces) from Salts Cave, Kentucky. Such work also influenced botanists, as they undertook investigations of how aboriginal knowledge of plant use could have utility in the modern world, particularly in regard to medicinal applications.

Ethnobotanical and paleoethnobotanical research in North America increased substantially after Melvin Gilmore's 1930 founding of the University of Michigan's Ethnobotanical Laboratory as part of the Museum of Anthropology. In his role as Director of the Laboratory, he solicited plant remains from archaeological sites across North America, thereby expanding both the scope and availability of paleoethnobotanical analysis in the New World. Working out of this Laboratory, Volney Jones, who began as Gilmore's assistant

and subsequently became his successor, conducted extensive research in paleoethnobotany, with his early work on the study of desiccated plant remains from Newt Kash Hollow rock shelter in Kentucky demonstrating the potential of such work. Rather than presenting a simple taxonomic list, he identified a variety of wild and cultivated plants and discussed how size differences in various seeds (chenopod, marsh elder, and sunflower) might reflect wild versus cultivated plants; he also discussed possible resource use patterns of wild plants and described potential variation in the extent of the native prairie, thus demonstrating not only the wide research potential of such plant remains but also setting a standard for subsequent paleoethnobotanical research (Pearsall 2015).

As with the Old World, there was considerable interest in the origins and spread of New World agriculture, with much of the research oriented toward discovering the origins and spread of the Mesoamerican derived crops of beans, squash, and especially maize. Research into the evolution, domestication, and spread of maize was conducted primarily within Mexico and the American Southwest where arid climates and sheltered contexts enhanced preservation of botanical remains. Two of the earliest and most extensive Southwestern studies were Anderson and Blanchard's 1942 *Prehistoric Maize from Cañon Del Muerto* (Arizona) analysis of 222 ears of ca. 1500 year old maize and Mangelsdorf and Smith's 1949 article *New Archaeological Evidence on Evolution in Maize* describing the results of their analysis of 900 discrete maize specimens from Bat Cave in New Mexico. Mangelsdorf was also instrumental in work being conducted in caves in the state of Tamaulipas, Mexico. Pollen analysis also played a role, as illustrated by Sear's 1932 publication of *The Archaeology of Environment in Eastern North America*, in which he argued that maize expansion in this area was a result of climate shifts that favored its growth. Pollen analysis has also proven useful in identifying evidence for the early cultivation of maize, as have starch grains and phytoliths.

While considerable research was, and continues, to be oriented toward maize, beans, and squash, paleoethnobotanists were also interested in identifying and documenting the use of less well known domesticates. Indeed, the first study of a single crop plant was Volney Jones' study of cotton in the American Southwest. Similar research resulted in discovery of a range of other domesticates, including ragweed, pigweed, sunflower, and may grass in the eastern United States as well as agave, little barley, Mexican crucillo, and amaranth in the Southwest.

As with the Old World, the pace of New World paleoethnobotanical research quickened in the late 1950s and into the 1960s and has continued to remain strong. Texas A&M University paleoethnobotanist Vaughn Bryant, for example, has calculated that between 1876 and 1965 there were about 375 substantive works published on plant remains from New World archaeological sites; today such works number in the thousands. Much of this was a result of the development of New Archaeology and the concomitant increase in attention paid to ecological approaches to analysis and increased emphasis on environment, as well as the growth in archaeological research resulting from legal requirements and the rise of Cultural Resource Management studies. But the increase was also partially technological. Faced with a pit filled with extremely ashy fill, archaeologist Stuart Struever followed the suggestion of botanist Hugh Cutler, and the technique now known as flotation was born. Flotation refers to the gentle agitation of a sediment sample in a water bath so that charcoal and other plant materials float to the surface, where they can be collected. Whether done with a bucket and screen or a standalone high-efficiency closed-system machine, flotation is seen as the single most important technological development in paleoethnobotany (Pearsall 2015). Prior to flotation, the vast majority of analyzed remains were those large enough to be observed, and collected, during the course of an archaeological excavation. Flotation greatly enhances both the concentration and collection of botanical remains over this previous norm of the serendipitous discovery of a charred seed or piece of charcoal. Instead, paleoethnobotanists could now collect sediment and soil samples from which paleoethnobotanical remains could be extracted.

A final factor to this dramatic rise in paleoethnobotanical research was the wider application of archaeological pollen analysis (Dimbleby 1985), the discovery (or, more accurately, the rediscovery) of phytolith analysis, and the incorporation of starch analysis into the paleoethnobotanical repertoire.

Both the range and scope of paleoethnobotanical analysis has continued to grow. In the 3rd edition of *Paleoethnobotany: A Handbook of Procedures*, Deborah Pearsall (2015: 30–31) well illustrates the thematic growth within paleoethnobotany. Her "sampling" of research topics includes (along with accompanying references): advances in identifying cultivated plants; identifying beverages; the use of wild foods by agriculturalists; wood acquisition, use, and environmental impact; plants and political complexity; plants as indicators of ethnicity; fiber and wooden artifacts; spices; plants in ritual; agricultural practices; plants in economic (trade and exchange) systems; and human environmental impacts, management, and land use. As Pearsall (2015: 34) states, "paleoethnobotany is undergoing a period of rapid growth and development, with exciting new areas of research and increasing quality of work in traditional areas of interest."

Data Sources

Four main categories of plant remains are found within archaeological sites: macrobotanical remains, organic residues, phytoliths, and pollen. What is particularly beneficial is the fact that these four data sources are much more strongly complementary in the sorts of information they provide than they are redundant.

The discipline of paleoethnobotany developed around macrobotanical remains, also known as macroremains, and such remains continue to lie at the core of paleoethnobotanical research. Though macrobotanical remains are large enough to be seen by the naked eye, their analysis typically employs microscopy. In the early days of paleoethnobotanical research, such remains were observed and collected during the course of an archaeological excavation. More recently, fine screening and especially flotation of soil and sediment samples have become the primary sources of macrobotanical remains.

While various fibers may be recovered from archaeological sites, macrobotanical remains most commonly consist of wood and seeds (which includes nuts, achenes, and similar plant parts). Most seeds decay within a century or so, even in relatively arid climates, so such remains are typically preserved through desiccation, charring, or waterlogging (Minnis 1981). The dry caves of the American Southwest and Great Basin are well known for the incredible preservation of organic materials, and some amazing results have been derived through the analysis of water logged assemblages – including Heer's pioneering work in Switzerland – but most macrobotanical assemblages consist of charred remains.

In some cases, it may be difficult to readily distinguish between modern and ancient seeds, particularly with desiccated and waterlogged assemblages. Charring is often readily observable, though distinguishing between charred and uncharred examples of black seeds like chenopods and amaranth may be difficult. Consequently, the context of discovery and comparison of recovered seed assemblages to modern vegetation can be of considerable utility in separating ancient from modern assemblages.

Minnis (1981) identified three main sources for seeds in archaeological sites: directly from resource use, indirectly from resource use, and from the natural seed rain. Direct resource use reflects seeds brought into a site to be used. These could be seeds that were themselves the desired product, such as amaranth seeds, or the waste product of resource use, such as fruit pits. Indirect resource use reflects the incorporation of seeds where the desired product was the plant, but not the seed, such as seeds falling from a thatch roof. The use of animal dung for fuel is a particularly interesting case in this regard. Animal dung was an important fuel source in various locations, such as the Great Plains of North America, where wood fuel was relatively scarce. Burning of this fuel in hearths or other thermal features can result in charring of seeds that passed through the digestive tract of the animal and were deposited in the

dung. This is of particular concern as one might reasonably concluded that charred seeds found within a hearth or other thermal feature reflect direct resource use, an erroneous interpretation in this case. Fortunately, experimental and ethnoarchaeological studies have proven to be of considerable aid in addressing this potential problem (Pearsall 2015).

As with seeds, very wet and very dry conditions will preserve wood, but most archaeological wood is preserved through charring; such charred wood is typically referred to as charcoal. Anthracology, or the study of charcoal from archaeological sites, has yielded substantive information on both paleobotany and human–environment interaction. Recovery of charcoal from thermal features provides excellent data on fuel use, how different wood taxa may be favored seasonally or by use, and how these patterns may (or may not) change through time, while charcoal from other contexts provides information on wood used in construction (structural wood) or tool manufacture. Anthracological assemblages have also been used to reconstruct past vegetation patterns, though there is some debate about the accuracy of such research.

Various factors affect charcoal representation, one of the most critical being source plant abundance. Other factors affecting representation include the abundance of dry dead-wood, rate of regeneration following harvesting of living trees, ease of harvesting and processing, the means by which wood is obtained, intended use, burning qualities, as well as cultural beliefs and perceptions about wood use.

In general, in addition to insight into plants that were growing in the area, analysis of macrobotanical remains routinely provides information in regard to plants cultivated, collected, and consumed as well as those used as fuel, in the construction of shelters, for making various types of tools and other artifacts, and for medicinal purposes, as well as possible information on trading patterns and religious observations.

Palynology contributes to a broad range of scientific research, including plant taxonomy, plant evolutionary relationships, forensic science, allergy studies, and archaeology. Its predominant use, however, has been in investigating vegetation history, to reconstruct ancient vegetation patterns and document their change through time and then use such reconstructions as proxy measures of paleoenvironmental and paleoclimatic conditions. But it also has considerable utility for paleoethnobotanical analyses.

Palynology is the study of pollen grains and spores. Spores and pollen grains are both very small, typically between about 20 and 50 μm (microns) in size, roughly half the diameter of a human hair. Spores are produced by nonflowering plants, bacteria, fungi, and algae. Pollen grains are produced by seed plants, or spermatophytes, which are comprised of two groups, angiosperms and gymnosperms. The former are the flowering plants, producing seeds within the female reproductive part of the flower, while seeds of the latter develop inside cones. Pollen grains are roughly homologous to mammalian sperm, and each grain can only successfully achieve its biological function if transported from the anther, the male part of the flower, to the stigma, the female part of the flower, of a conspecific plant where it germinates and subsequently fertilizes an egg. Regardless of the transport mechanism, there is only a very slim chance that any given pollen grain will reach the stigma of a conspecific. Consequently, pollen grains are produced in great abundance, though anemophilous (wind-pollinated) plants produce much more pollen than do zoophilous (animal-pollinated) plants. One cone of *Pinus contorta* (lodgepole pine), for example, contains almost 600,000 grains and a 10-year-old branch system of *Pinus sylvestris* (Scotch pine or Finnish pine) has been estimated to produce about 350 million pollen grains annually. Zoophilous plants generally produce far fewer pollen grains and rely on some animal (bats, birds) or insect (chiefly bees) to transport the pollen from the anther of one flower to the stigma of another. An evolutionary outcome of this presumably more efficient pollination method is decreased pollen production, say approximately 1000 or fewer grains per anther compared to the 10,000 to 70,000 grains per anther with anemophilous plants.

Pollen of anemophilous taxa can be transported and deposited hundreds of meters and

sometimes kilometers or even hundreds of kilometers from their source. Therefore, anemophilous pollen is both much more abundant and much more widely dispersed than zoophilous pollen, although the latter may be occasionally locally abundant in soil samples because of flowers dropping after anthesis. Hence, anemophilous plants stand a far greater chance of being observed in the pollen record of a sediment sample. Consequently, pollens from zoophilous taxa are often poorly represented in a pollen record, even when such taxa dominate the vegetation.

Nevertheless, the fact that pollen grains are abundant and, at least for anemophilous taxa, are widely distributed in the environment is one of the characteristics that makes them so suitable for paleoenvironmental analysis. A second characteristic that makes them of value is that the amounts observed vary with the number and proximity of the source plants. Third, pollen grains are durable, and fourth, they are morphologically distinctive. Finally, and of crucial importance for paleoethnobotanical studies, their amounts are affected by human activity. Thus, in addition to its use in reconstructing past vegetation patterns and inferring past environmental conditions, pollen analysis is well suited to documenting plants cultivated, collected, consumed, or used in rituals. Further, palynology can provide data on plant use not available from the macrobotanical record.

In the American Southwest, for example, cholla cacti were a very important part of the prehistoric diet, but are seldom seen in the macrobotanical record as the desired product – flower buds – are unlikely to be preserved. Instead, unusual frequencies of cholla pollen are required to document cholla use, as harvesting and processing of cholla flower buds often introduces relatively large numbers of cholla pollen grains into cultural settings. Systemic patterns in regard to the distribution and abundance of cholla pollen, and their deviance from those expected as a consequence of natural patterns of pollen production and dispersal, are used to identify unnatural occurrences of such pollen and evidence of resource use. As the quantity and quality of resource-use patterns accumulates, the ability to distinguish between those patterns associated with cultivation and those derived from collection may also become more apparent.

Typically, pollen samples employed in the analysis of past vegetation and for reconstructing paleoenvironmental conditions are obtained from sediment cores collected from lacustrine basins and peat deposits. Such paleovegetation and environmental reconstructions have long been of use to archaeologists as knowing the environment in which people lived is of fundamental importance. Such research has also proven crucial in documenting human impacts on vegetation, particularly land clearance accompanying the introduction of agriculture (Fish 1994; Magyari et al. 2012). However, most paleoethnobotanical applications of pollen analysis involve the analysis of terrestrial samples derived from archaeological sites and features.

Differential preservation and movement of pollen across stratigraphic layers has been raised as a concern in terrestrial pollen analysis. In his classic text on archaeological palynology, Dimbleby (1985) raised dual concerns about pollen downwash through percolation and increased bacterial-induced degradation through time. Therefore, the pollen record of any given stratum was argued to consist of the originally deposited pollen minus pollen more prone to destruction and those transported to greater depths, while being augmented by less fragile pollen transported into the stratum from overlying strata. Total pollen concentration would, therefore, decrease with depth, while the proportion of resistant pollen types increased, such that upper layers would have greater taxa richness than lower ones (Fish 1994: 48; Dimbleby 1985). Dimbleby (1985) also cautioned that soil-mixing organisms such as earthworms could transport significant amounts of pollen. Evaluation of these concerns is warranted, and various researchers have responded to Dimbleby's arguments.

In one of the few systematic evaluations of pollen downwash, however, Davidson et al. (1999: 652) found "no evidence that downwashing of pollen is significant in [five different soil types] despite the soils exhibiting great contrasts in hydrological regime and degree of water-table fluctuation." Further, in a general discussion

of archaeological palynology, Bryant and Holloway (1996) did discuss sediment mixing and its effects on pollen, but primarily by rodents and as a result of cultural activities; downwash was not mentioned. Yet, Kelso et al. (1995) argued that pollen downwashing and destruction was of concern in a seventeenth-century refuse pit, though Fish (1994) argued that such percolation, destruction, and mixing was an extreme case. Nevertheless, given that significant alteration of the pollen record can occur, if rarely, Fish (1994) recommended evaluation on a case by case basis, a perspective subsequently seconded by Pearsall (2015). On the other hand, research has clearly illustrated that earthworms and ground nesting bees may affect pollen records in terrestrial samples (Davidson et al. 1999). Intriguingly, earthworms have also been documented to have potentially serious deleterious effects on the preservation of small (<2 mm) carbonized seeds. Overall, however, while caution need be applied in interpreting terrestrial samples, "a variety of evidence strongly suggests that processes threatening the stratigraphic integrity of pollen assemblages are neither as pervasive nor as serious as Dimbleby's model suggests . . . Indeed, there are few adherents of this [model] among a large body of North American practitioners engaged in archaeological and non-archaeological research" (Fish 1994: 49).

As interest in palynological evidence of landscape conditions and land use patterns has developed during the past several years (Gaillard et al. 1992), it became increasingly evident that pollen analysis of terrestrial samples may offer significant potential for study of prehistoric agriculture. As indicated above for Denmark, European pollen analysts have tended to approach the problem through identification of changes in the temporal and spatial distributions of arboreal versus non-arboreal pollen plus the presence of crop plant and field weed pollen types in sediment cores recovered from lakes and ponds. Fish (1985) developed a more direct approach by determining unique features of samples recovered from prehistoric field contexts themselves. She found that though the pollen taxa recovered from irrigated Hohokam field-deposits were not different from those recovered in samples from Hohokam habitation contexts or modern Sonoran Desert pollen rain, percent values for three taxa were distinctive in irrigated field contexts. She thus recognized a palynological "signature" for this type of cultivation, which may be used to identify such fields in samples from locales where other forms of material evidence may not occur. Fish's palynological signature for Hohokam irrigated fields is quantitatively, rather than qualitatively, unique. Though she did not employ quantitative techniques, Fish's signature constitutes the sort (type) of quantitatively identifiable pattern which is amenable to discovery through application of such techniques. Her research was also at least partially responsible for the development of more intensive and extensive examination of terrestrial deposits associated, or potentially associated, with ancient agricultural practices at a variety of Sonoran desert sites (Fish 1985; Stuart 2007).

While a great deal of pollen analysis in paleoethnobotany has been oriented toward agriculture, pollen analysis can also be of considerable benefit in documenting feature type and use, particularly when combined with other paleoethnobotanical approaches. Further, artifacts themselves are amenable to pollen analysis through pollen washes, that is, the washing of sediment from within the scratches and depressions of an artifact, typically groundstone, into a receptacle and then processing the contents to extract the pollen, and phytoliths as well. While pollen washes of artifacts can be productive, there are a series of variables (plant taxa, storage practices, processing type or stage, tool curation, processing context) that need to be considered during interpretation.

The earliest research on phytoliths from archaeological sites commenced as the nineteenth century gave way to the twentieth and involved identifying cultivated Old World grasses (Netolitzky 1900, 1914 and Schellenberg 1908 cited in Pearsall 2015). Curiously, paleoethnobotanical applications of phytolith research in the New World did not occur until several decades later. The earliest research again occurred in Peru, with the 1960s investigations at the Kotosh site (Matsutani 1972 cited in Pearsall 2015).

Following publication of Rovner's "seminal" article *Potential of Opal Phytoliths for use in Paleoecological Reconstruction* in 1971, however, interest in phytolith research began to expand significantly, roughly contemporaneously with expanding interest in the origins of New World crops and paleoenvironmental reconstruction (Pearsall 2015: 265).

Phytolith research involves the recovery, identification, and interpretation of plant opal silica bodies preserved in archaeological contexts (Pearsall 2015: 253). Phytoliths are microscopic silica bodies that form in many living plants, and many of these forms are morphologically distinctive. There is some redundancy in phytolith form within some families, particularly the grasses, but even within the grasses different subfamilies and classes can be distinguished, which is certainly an improvement over pollen analysis of grasses.

Furthermore, different phytolith forms may arise in different parts of the plant. Phytoliths that form in the roots of maize plants, for example, are morphologically different from those that form elsewhere in these plants; this fact has proven helpful in identifying the location of prehistoric agricultural fields, particularly when such phytoliths are found in conjunction with high concentrations of maize pollen.

In contrast to pollen, phytoliths are not part of the plants' reproductive process and therefore are not dispersed into the environment in the same way as pollen. Though phytoliths do become effectively airborne – Charles Darwin noted their presence in dust collected from the research vessel HMS Beagle – for the most part phytoliths are deposited locally as the source plant decays. Similarly, phytoliths enter an archaeological context through decay or burning of the source plant, but also through a plants consumption and subsequent release (that is, in coprolites or in soil from the abdominal area of a burial). Once deposited, phytoliths usually remain close to the point of deposition, though soil movement and formation processes may have an effect on final placement. As they are inorganic, phytoliths tend to be resistant to decay and therefore may be preserved in circumstances detrimental to organic preservation. Consequently, their study can be quite complementary to pollen and macrobotanical analyses.

Phytoliths can often be extracted from the same sediments used in pollen analysis and as with pollen can provide a range of information of interest to archaeology. Their accumulation in stratigraphic and archaeological deposits provides data on plant-people interaction, paleoenvironmental conditions, and human environmental impact. Isotopic analysis of phytoliths can also aid in reconstructing past vegetation and identifying climate change. Specific to archaeological sites, phytoliths have been used to identify spatial variation in human activities and plant composition of the diet. Phytoliths can be recovered from stone and ceramic artifacts, aiding in discussions of tool function and plant use. Phytoliths can also become incorporated into dental calculus, providing information in regard to diet and dental health. They are also routinely recovered from coprolites providing yet another source of information on diet. Though composed of silica, phytoliths also contain carbon and can be radiocarbon dated, though there has been some concern about the incorporation of ancient carbon into phytoliths resulting in anomalously old dates.

Organic residues include a broad range of materials, and though all are microscopic they range from organic molecules and compounds, through cells, to fragments of bone and wood. Organic residues of both plants and animals are sometimes preserved in sediments and on the surfaces and in the cracks of stone tools and ceramics, where they provide information on resources used and artifact function. Plant residues consist of a wide range of minute particles including proteins, lipids, tannins, raphides, cells and cell fragments, starch grains, fibers, and wood fragments. Though the presence and utility of organic residue research for stone tool analysis was demonstrated in the 1970s, application of organic residue analysis was not common until relatively recently, though incorporation of such studies has since grown rapidly. Though various problems have been encountered in residue analysis, experimental research and incorporation of new methods continually result in improved techniques and results (Pearsall 2015).

Starch grains are tiny granules that are the main energy source for plants, and one of the most commonly studied plant residues. Some starch grains, called storage starch, are quite durable and continue to exist long after the plant itself has died and rotted away. In this regard, they are quite comparable to phytoliths. Starches may be recovered from soil samples, or collected off of artifacts. Contamination issues, however, have been raised in regard to the application of starch research, though research into overcoming these difficulties continues.

As with starch grains, the use of an artifact to process some plant (or animal) resource will result in the transfer of proteins from that resource onto the artifact, and some of that protein may remain preserved on the artifact. Even minute quantities of such protein can be identified, providing important insight into artifact use.

Though not a data source per se, coprolites – often described as fossilized fecal matter though preserved fecal matter might be more accurate – are deserving of particular mention. Human coprolites provide the most direct evidence on diet and health available from the archaeological record. Though the digestibility of different foods influences what passes through the digestive system, they nevertheless provide clear evidence of dietary choices. Further, those choices reflect what was eaten over an archaeologically extremely brief period of time. The short period of time reflected and the clear association with human activity make coprolites a highly unusual archaeological resource.

They are also a rich source of paleoethnobotanical material. Pollen, phytoliths, and seeds have all been recovered from coprolites. Seeds found in coprolites almost certainly reflect conscious choices in regard to diet. While phytoliths can become airborne and therefore may be accidentally ingested, it is more likely that their presence reflects diet, particularly if present at moderate to high concentrations. Pollen may reflect diet, consumption of beverages, or simply the breathing in of pollen grains, but again high concentration values or percentages, particularly of zoophilous taxa, are more likely to reflect intentional ingestion.

Coprolites have been used to evaluate a range of topics, including diet breadth, relative importance of wild versus domesticated foods, medicinal use, season of occupation, mobility patterns, and through the use of fecal steroid analysis even the sex of a site's occupants. Plant remains in nonhuman coprolites can also be quite useful. Akeret et al. (1999), for example, analyzed pollen and macrobotanicals from goat/sheep coprolites to document foddering practices at Arbon Bleiche 3, a Neolithic lake-shore settlement in Switzerland. Such analyses also provide information on animal diet and paleovegetation.

The discovery that DNA may be preserved in the uncharred interior remnants of carbonized plant material, as well as in dried and waterlogged specimens, provides another avenue into the study of paleoethnobotanical remains. Such research could play a critical role in identifying specimens whose morphological characteristics are ambiguous, investigating the evolutionary history of domesticated plants, documenting trading patterns and the introduction of new species, and achieving a better understanding of the process of domestication, among other topics. Similarly, the analysis of ancient environmental DNA collected from terrestrial sediment samples or lake cores has considerable potential for assisting in reconstructing past vegetation patterns and paleoclimatic conditions.

Key Issues

Consistent with other branches of archaeological investigation, a key issue among paleoethnobtanists concerns the representativeness of their samples. While sampling methods have improved to help ensure more uniform coverage and inclusion of all pertinent contexts, concerns over "missing" data still occur. A critical factor to keep in mind in reviewing any paleoethnobotanical analysis is that the plant remains found at a site do not directly reflect all plant use at the site. Similar to other archaeological materials, the plant remains recovered from a site are a biased sample as a result of the vagaries of production, deposition, preservation, and recovery. Though

paleoethnobotanists are well aware of the limitations of their data, such limitations are not always explicitly presented and discussed within the context of a report or published article. Differential preservation as it relates to archaeological palynology was discussed above, but such concerns apply equally to other paleoethnobotanical data sources. Many macrobotanical remains, for example, are more likely to be preserved by charring, but many others are used in circumstances that are less likely to allow for such preservation; roasting of maize enhances the possibility of producing charred remains, boiling a pot of beans does not. Even in those plants for which charring is more likely to occur, there are fine lines between sufficient levels of carbonization to char and therefore preserve a macrobotanical specimen and those that result in either excessive charring leading to destruction or insufficient charring allowing natural degradation.

Paleoethnobotanical remains are also susceptible to postdepositional movement and other taphonomic issues. Assessing these effects has long been of interest, but only recently has experimental research to gain better understandings of the taphonomic processes affecting macro- and microbotanical specimens been conducted (Wright 2010).

Another key issue in paleoethnobotanical research is the source of the plant material and differentiating between natural deposition such as through environmental pollen and seed rain, and anthropogenic deposition. Extramural features, by nature of being outside of structures, likely had greater exposure to and thus greater opportunity for deposition of seeds, pollen, and phytoliths from a variety of native plant species, especially weedy taxa. Inadvertent introductions of plant remains within thermal features and their subsequent charring during feature use may occur; hearth use has also been noted to cause charring to seeds in sediments adjacent to but outside of the feature itself. Although there is no clearly defined procedure to determine whether plant remains entered a deposit through intentional use or accidental incorporation, knowing that both occur tempers conclusions reached. It seems likely, however, that separating anthropogenic from natural depositions of seeds and even phytoliths is less of an issue than differentiating between anthropogenic and natural signatures in pollen assemblages.

While abundant production and widespread distribution of pollen is a key reason that pollen has been used for reconstructing past vegetation patterns, it also means that pollen is routinely and naturally deposited onto archaeological sites and within archaeological features. In cultural settings, however, pollen assemblages are also affected by human activity. Often this activity directly affects the local source vegetation, enhancing and expanding suitable locations for some plants, while degrading and reducing suitable locations for others. Impacts on the vegetation associated with clearing the land for agriculture or construction, the introduction and use of irrigation or other forms of disturbance, and the cultivation – or at least encouragement – of selected native taxa are prime examples. Further, amounts of local pollen, and probably phytoliths, can be augmented and nonlocal pollen and phytoliths introduced through the collection of comestibles, fuel wood, or construction materials or, in the case of historic assemblages, the introduction of exotic nonnative taxa. While of anthropogenic origin, many of these alterations of and additions to the pollen and phytolith records may not necessarily relate directly to activities associated with the feature or structure from which the remains were obtained. Thus, any given sample may contain pollen, and perhaps phytoliths, from the natural pollen (or phytolith) rain, incidental anthropogenic pollen, and phytoliths arising from various activities conducted within the site and surrounding area, as well as anthropogenic pollen and phytoliths deriving directly from activities associated with the location from which a sample was derived. Separating these different components remains an issue for samples from archaeological sites. One manner in which paleoethnobotanists approach the problem is to look for unusually high percentages or concentrations of pollen grains or phytoliths, particularly in taxa of known economic importance. Quantitative analyses, such as correspondence and detrended correspondence analysis, and incorporation of

modern pollen records of known ecological/human context, have also proven useful in this regard (Gaillard et al. 1992; Stuart 2007).

A key means by which one can evaluate and delineate natural from anthropogenic constituents in the paleoethnobotanical record is to look at multiple paleoethnobotanical data sources in combination with the associated archaeological record. While it is a given that various cultural and natural factors produce patterning in paleoethnobotanical assemblages, feature use will be a significant source of such patterning. One would expect, for example, that a roasting pit might have a very different paleoethnobotanical signature than a storage pit or a structure floor because of behavioral differences in how these features were used; empirical research suggests this is indeed the case. It is also desirable to have several samples from similar feature types and depositional contexts, as well as samples from nonfeature contexts, for comparative purposes and to control for stochastic effects.

It is also worth noting that interpretations of paleoethnobotanical data can be enhanced through ethnographic analogy and ethnoarchaeological data, though their application needs be done carefully. Paleoethnobotanists typically use such data to document how plants were used by "traditional" peoples, and then extrapolate such use into the past. Paleoethnobotanists can then turn to other aspects of the archaeological record, such as associations between particular species of seeds and grinding tools, to help confirm or negate these hypothesized uses. Of course, the reverse is also common, where paleoethnobotanists find particular species of seeds in association with grinding tools and then turn to the ethnographic record for documentation supporting a hypothesis of resource use.

Thus, interpretation of paleoethnobotanical assemblages requires accumulating a diverse ecological and archaeological skill set, as was proclaimed by Jones (1941) decades ago. More recently, Bryant and Hall (1993: 279) echoed this perspective, stating that archaeological palynology is "an apprenticeship science where a novice works with and learns from a skilled professional." As Pearsall (2015: 33) indicated even more recently, "this applies to paleoethnobotany as a whole." This apprenticeship is worthwhile, however, as paleoethnobotany is well positioned to address a broad range of questions in regard to settlement and subsistence variability, socio-natural systems, human–environment interaction and impacts, the use of space, social uses of food, economic systems, and a whole host of other topics.

Future Directions

The days of providing a catalogue of plants recovered from an archaeological investigation are long gone. While the basic theme of the interrelationship between people and plants remains, both the data sources and theoretical and methodological aspects of paleoethnobotany have become increasingly sophisticated. Though paleoethnobotany originated with the study of macrobotanical remains, additional forms and types of plant remains began to be recovered from archaeological sites, to the point where paleoethnobotany now includes molecular studies and the analysis of ancient and modern DNA. Simultaneously, increasingly sophisticated techniques both in the field and in the laboratory have resulted in dramatic improvements in our ability to assess morphological changes in ancient and often fragmentary archaeobotanical remains while simultaneously adding in the interpretation of taphonomic processes and context (Langlie et al. 2014: 1601).

This has provided a wealth of information, but has also led to increasing specialization within the field, with pollen analysts, phytolith analysts, starch analysts, macroremain analysts, and more. As Pearsall (2015: 28) noted, it is difficult to master more than one or two of these, and impossible to master them all. Consequently, interaction between paleoethnobotanists – and with geneticists, biochemists, paleobiologists, paleobotanists, and archaeologists – is crucial, and collaborative research is the developing norm. Within paleoethnobotany, macrobotanical and microbotanical research are more and more frequently being employed together (VanDerwarker et al. 2016), a positive trend which is likely to

continue. Results of paleoethnobotanical research and paleoethnobotanical data are also becoming more fully integrated with other data sources. This seems likely to continue as such collaborative research reflects a clear example of the whole being greater than the sum of the parts.

While the ongoing incorporation of new data sources and techniques into the future of paleoethnobotanical research is welcome, some modification of traditional approaches to paleoethnobotanical analysis would also be welcome. While standardization of protocols, rigorous sampling strategies, and quantitative analyses of macrobotanical and microbotanical assemblages continues to improve (VanDerwarker et al. 2016: 155), it is unfortunate that sampling procedures and quantification methods still vary enough from site to site and researcher to researcher to make direct comparison of results sometimes difficult. These problems have long been known, but a definitive means by which to address them has not been forthcoming. Perhaps as research continues to develop, paleoethnobotanists will be able to devise means by which to both improve standardization and use of common protocols, but without stifling innovation.

At least as pressing a problem as greater standardization is the role of the paleoethnobotanist. Or more particularly, at what stage in a research project a paleoethnobotanist is included. While paleoethnobotanists do run their own projects and collaborative research has clearly increased, it still remains the case that quite often, especially within cultural resource management projects, that samples are shipped off to a paleoethnobotanist for analysis without her having been part of the original planning or excavation; indeed, often they are sent without inclusion of information in regard to the research questions and research design. Ideally, "analysts" (and not just paleoethnobotanists) should be involved in all aspects of the project, from formulation, planning and identifying research questions, through excavation, on-site sampling, and subsequent selection of samples for analysis. When involved in a project from the beginning and with greater knowledge of the goals of the project, the better can paleoethnobotanical data be integrated into the project and used to more clearly address questions posed in the research design. Indeed, if integrated into the project from the beginning, the paleoethnobotanist can help formulate and refine the research design and therefore contribute more directly to and facilitate achieving of the project's research goals.

Future developments within paleoethnobotany will also be directed by developments within the broader field of archaeology. One topic of growing interest that has significant potential to affect paleoethnobotany involves human environmental impact and adaptation to changing climates. Humans have been an integral and active component of earth's ecology for many thousands of years. This long history of interaction between humans and their environments has had both deleterious and positive impacts, for us, other species, and the landscape itself. By studying the dynamic ecological role of human society and how humans impacted their environments in the past, we gain a better appreciation of the potential effects of our own activities and their environmental consequences. Many of the processes affecting the planet today are deeply rooted in our past, as many of the actions we see today – deforestation and land clearing, over-grazing, erosion, soil salinization, and loss of fertility, for example – were produced by and had impacts upon past peoples. Often, it was the combination of these human impacts occurring simultaneously with climate change that led to the collapse of past civilizations. Much of the knowledge we have about such cases derives, at least in part, from paleoethnobotanical research. Therefore, paleoethnobotanists have an important role to play as research into coupled socio-natural systems continues to develop and scholars continue to explore how the complex long-term interplay between ecological processes, human institutions, and changing climate affected past societies and their environments. Indeed, this may be one of the more crucial research endeavors to which paleoethnobotanists can contribute. A better understanding of how these situations arose in the past, and the sorts of environmental, political, and social consequences that they had may help us to better discern general principles that continue to operate today, and thus plan toward our future.

Paleoindians

Christopher J. Ellis
Department of Anthropology, University of Western Ontario, London, ON, Canada

Introduction

Paleoindian (also spelled Paleo-Indian, Palaeo-Indian), or literally "Old" or "Ancient" Indian, is a term widely employed to refer to the archaeological record of the Americas dating to the Late Pleistocene to Early Holocene from as early as perhaps 11,500 ^{14}C years BP to as late as 8,000 years BP in some areas (13,500–8,800 calibrated years BP). The term is often used to distinguish this segment of the archaeological record from that of potentially earlier dating, "Pre-Clovis" peoples, and later-dating, Post-Paleoindian "Archaic" and other peoples. A basic distinction has often been made, particularly in North America, between "Early" Paleoindians (prior to c. 10,400–10,100 BP), who produced distinctive, flaked, lanceolate, stone point tips with grooved or fluted bases (see Fig. 1), and "Late" Paleoindians (after c.10,400–10,100 BP) who made unfluted

lanceolate and stemmed points. Many different and finer Paleoindian regional/temporal subdivisions, variously referred to as cultures, complexes, industries, or phases, also have been suggested of which the earliest well-established and most widespread subdivision is Clovis, dated c. 11,000 ^{14}C years BP. Such distinctions have been made primarily on the basis of differences in the stone point assemblages although other, usually more subtle, differences in stone tool kits and production technology are present. For example, only Clovis Paleoindians seem to have employed a true blade technology.

Definition

The term Paleoindian was first used by Frank H. H. Roberts Jr. in the title of a 1940 paper. He did not define the term and only used it once in the text in the last line of that paper. Yet, it was clear that he was using the term in a general sense to refer to any archaeological evidence that existed at that time that seemed to be of considerable antiquity and thus had a bearing on when the Americas were first peopled. This evidence included the famous discoveries of the previous 13 years at sites like Folsom and Clovis, New Mexico, and

Dent and Lindenmeier, Colorado (for a summary, see Wormington 1957), where the distinctive point tips and other exquisitely made stone artifacts had been found in Late Pleistocene contexts, often in kill sites in association with extinct megafauna such as mammoths and large bison species. However, Roberts (1940) also discussed sites that were apparently of some antiquity but yielded less well-made lithic assemblages that often included smaller, non-lanceolate point forms, cruder choppers and scrapers, and even, on occasion, grinding and milling stones.

Only rarely do current researchers use the term in Roberts' (1940) general sense. In most quarters the term has come to be used in more limited and specialized ways. In the 1950s there was an increasing tendency to restrict the usage of the term Paleoindian to assemblages that not only were of some antiquity but also could be separated out from later or even potentially earlier ones in terms of certain characteristics. Particularly stressed were characteristics of the archaeological record itself, such as the kinds of artifacts produced and distinctive aspects of the sites, or in terms of ideas about the lifeways (e.g., subsistence and economic practices) and other aspects of the cultural systems of these groups.

In terms of the artifact record, today's scholars stress the presence of the stone lanceolate or lance-shaped point tips and, particularly in some slightly later-dating assemblages in areas such as the Plains, Great Basin, and South America, stemmed forms – points with side or corner notches for hafting to the weapon shaft are absent; a stone tool kit dominated by more formalized, extensively retouched/resharpened tools such as bifaces, side scrapers, and hafted end scrapers; overall excellence in flint-knapping skill; the selection of only the highest grades of flakeable stone materials ("cryptocrystallines"); a tendency to transport toolstones over long distances; the use of standardized core reduction techniques including true blade industries in the earliest well-established Paleoindian development (e.g., "Clovis") as well as more generally the use of large biface cores; an absence of ground and polished stone tools; and, at least to some (e.g., Krieger 1964), an absence of food-grinding implements used in plant processing. To this list I would add the regular use of thick edges produced by the purposeful snapping or radial breakage of bifaces and flakes, the consistent presence of certain kinds of other distinctive artifacts such as large side scrapers and well-made needlelike micro-piercers and borers ("gravers") (Fig. 2) and, for some reason, a real absence or rarity of fire-cracked/broken rocks used in heating and cooking. The last named is a major contrast with subsequent Archaic and other sites.

Paleoindian sites themselves are seen to contrast with those of their later descendants in that they are rare and ephemeral with little evidence for substantial structures or other features. However, utilitarian, as well as apparently sacred, caches of stone artifacts are proving to be especially common (e.g., Deller et al. 2009). The sacred caches or offerings can be purposefully broken either by heating or by deliberate smashing (e.g., Fig. 3) and some are accompanied by red ochre. Where preservation is suitable, a very few of the sacred caches are accompanying burials but in other cases they are not. Using minimally the presence of the distinctive, well-made stone points as a defining characteristic, Paleoindian sites can be found throughout all of unglaciated North America of the time, both south of the ice sheets and in Alaska, all of Central America, and, more spottily, in areas of South America such as the southern cone and northwest parts of that continent.

The small size and ephemeral nature of most sites, the use of exotic toolstones from distant sources, the employment of standardized core reduction techniques that some have interpreted as resulting in a more efficiently produced and portable tool kit, etc. have often led to the inference that Paleoindians lived in small groups and practiced a highly, mobile lifestyle, moving their camps frequently and over a large area annually. Such characteristics are frequently related to the arguments that Paleoindians were the first major occupants of the area, were involved in colonizing new regions, and lived at low population

Paleoindians, Fig. 2 Paleoindian unifacial stone tools from various sites in the Province of Ontario and New York State. densities. Also, as the first reported sites in the Western USA were almost all kill sites of large game, along with an absence of food-grinding implements, it was often inferred that these peoples relied much more on hunting than did later groups such as those of the Archaic (e.g., Mason 1962; Krieger 1964). Some even went so far as to suggest or use alternative terms for Paleoindian such as "Early Hunter" or "Early American Hunters" to reflect this inferred lifestyle.

These definitions based on inferred cultural characteristics such as mobility and subsistence practices, while popular, have been and continue to be problematic, especially when applied at continental scales. For instance, many later Plains Paleoindian groups do not seem to have relied much on exotic stones nor on standardized, purportedly more portable, core forms like bifaces, suggesting they had a less mobile lifestyle (e.g., Bamforth 2002). Also, many have questioned the idea that Paleoindians were primarily big-game hunters, notably in areas such as the American Southeast, the Great Basin, or much of South America. In these cases, there often have been calls to abandon the use of the term Paleoindian to refer to these early peoples. In the Great Basin, for example, while some lithic assemblages seem technologically Paleoindian, settlement pattern data, paleoenvironmental data, and faunal recoveries suggest a broader resource focus leading to investigators calling certain assemblages "Paleoarchaic" (for discussion, see Madsen 2007). In South America, a lack of substantial evidence for a big-game hunting focus in many areas has led some to conclude that Paleoindian is a term that cannot be easily applied there and terms such as "proto-Archaic" have been suggested as alternatives (e.g., Dillehay 2000: 7–8). However, it is worth stressing that there is evidence that does suggest some of these early groups, such as Clovis in the Southwest USA, seem to have relied relatively heavily on larger game such as mammoths (Waguespack and Surovell 2003). Apparently the Paleoindian flaked stone technology was a very flexible one, capable of use in a wide range of subsistence and economic contexts.

Key Issues/Current Debates/Future Directions/Examples

Beyond the long-standing problems of the exact nature of their lifestyle/economic organization and of providing a rigorous, consistent definition, the use of the term "Paleoindian" itself also has become contentious. Some have suggested that these early peoples may have originated in areas such as western Europe rather than as, in the traditional view, east Asia/Siberia (see below). In addition, there have been studies of the limited early skeletal material that suggest the earliest peoples were morphologically different from more recent "Indian" populations. Hence, several recent scholars prefer the term "Paleoamerican" (Meltzer (2009: 175–6, 205) reviews these issues and in agreement with him, I am not impressed with their rationale). Also, the indigenous scholar Eldon Yellowhorn (2003: 62) has argued that the use of the term Paleoindian should be replaced with the term "Paleolithic" to achieve "the objective of placing Aboriginal peoples on an equal basis with other early peoples elsewhere in the World."

Perhaps the most contentious issue in Paleoindian studies concerns the origins of these peoples. The traditional view has been that Clovis Paleoindian peoples were the first inhabitants and this viewpoint is consistent with the widespread distribution of the distinctive Clovis technology over a very large area. Moreover, in the traditional view, Clovis technology is very much like that of the Asian (and European) Upper Paleolithic, notably in the inclusion of a true blade industry, the inclusion of burins (albeit very rarely such that some dispute that the reported Clovis examples are actually purposeful burins), and of similarities in organic technologies including the production of shaft wrenches and cylindrical points having on one basal side a beveled surface incised with cross-hatched lines. The genetic and physical evidence could be and was used to argue specifically for an ultimate origin in the East Asian/Siberian Upper Paleolithic. However, some have argued that more unique aspects of the Clovis archaeological record, such as the production of large bifaces that are thinned by repetitive, stylized

use of "overshot" flaking (e.g., large flake removals that are deliberately carried across the whole biface surface and actually detach a small area of the biface edge opposite the striking platform edge) or the caching of large bifaces, have closer analogs in the Upper Paleolithic of Europe, specifically in the Solutrean of Spain and France. This evidence leads them to argue for a European origin and that people crossed the north Atlantic Ocean along the edge of the ice sheets at the time to reach the Americas (Bradley and Stanford 2004). Needless to say, several scholars have objected to this idea, pointing out, among other things, that Solutrean material dates thousands of years earlier than Clovis and that all known Clovis biface caches are actually in western North America rather than in the presumed point of entry in the east (see Meltzer 2009: 185–8).

There have also long been claims of archaeological finds predating Clovis Paleoindian ones, finds that would undermine the "Clovis first" idea. Many of the earliest claimed sites were characterized by very simple flaked stone technologies that lacked stone projectile points and hence were often referred to a "Pre-Projectile Point" era (see Krieger 1964). However, the vast majority of those sites have been discredited or their status remains unclear. Yet, since the 1970s there have been increasing reports, albeit not undisputed, of Pre-Clovis assemblages dating c. 16,000–11,500 ^{14}C years BP window that do include points including lanceolate as well as smaller triangular forms and some sites are said to also include evidence of blade industries (for a recent summary, see Pitblado 2011) and even, in one case from Texas, the production of radial break and snapped edge tools (Waters et al. 2011). If so, then they might be plausible Clovis and other Paleoindian ancestors – the presence of these points and standardized core working would suggest they can be viewed favorably as Paleoindian per se rather than as simply "Pre-Clovis."

At a theoretical level, there has been a real tendency to explain the Paleoindian archaeological record in more materialist terms. For example, as hinted above there has been a preponderance of arguments that attempt to explain aspects of that record, such as technological characteristics, in terms of simply what Paleoindians were eating and/or how far and how often they moved across the landscape. However, as also indicated above, that viewpoint has become increasingly problematic or at the very least seems oversimplified – Paleoindian groups using similar technologies apparently had a diversity of subsistence and mobility practices. As such, and in line with more general theoretical trends within the discipline as a whole, there have been increasing calls for more people-centered approaches to interpretation that foreground more explicitly these peoples' beliefs, the construction of social identities, and more broadly their histories in order to understand why their archaeological record differs from that of other peoples (e.g., Ellis 2009).

Paleolithic Archaeology of Wales: Overview

Elizabeth A. Walker
Department of History and Archaeology, Amgueddfa Cymru – National Museum Wales, Cardiff, UK

Introduction

There are many caves in the Carboniferous limestone bands that stretch across South Wales from Gower to Pembrokeshire and in northeast Wales. Many of these caves have been used for human occupation in the past, and many of them have been investigated, either formally or informally, over the years. The results of this work enable a picture to be drawn together of a human presence in Wales dating back some 225,000 years.

Definition

The Paleolithic occupation of what is now Wales can be seen to span a time period from evolutionary early Neanderthals at Pontnewydd Cave, through the evidence for a true Neanderthal presence at sites that include Coygan Cave to the arrival of evolutionary modern humans at Paviland Cave, Cathole Cave, and Ffynnon Beuno before the Last Glacial Maximum. Humans withdrew from Wales during the coldest time of the Last Glacial to reappear when vegetation and a food source had once again reestablished themselves during the post-Glacial period, around 15,000 years ago. Their presence is not thought to have been continuous, there being a short gap in the sequence of evidence during the Late Glacial Younger Dryas stadial event, with humans reappearing after a gap of around 1000 years, never again to leave Wales.

Key Issues

Pontnewydd Cave, Denbighshire, defines the starting point for a human presence in Wales at around 225,000 BP (see Walker's EGA entry "▶ Paleolithic Archaeology of Wales: Pontnewydd Cave"). Excavations at Pontnewydd Cave have recovered the remains of 16 hominin teeth and one tooth fragment. These represent a minimum of five evolutionary early Neanderthal individuals aged from 8.5 years to mature adult. These hominins left behind over 1284 stone tools, among which is a Levallois technology accompanying Acheulian bifaces and an associated faunal assemblage. The activity at the cave suggests the main hominin activity that took place just outside the cave and that the people were expediently making use of local raw materials for their toolkits. There is no in situ evidence for these

early Neanderthals' presence at the cave. The deposits have all been washed into the cave during a series of debris flow events that took place sometime just before the development of the stalagmite floor. It is this stalagmite and thermoluminescence from burnt flints that date the hominin occupation at Pontnewydd Cave at 225,000 BP (Fig. 1; Green 1984; Aldhouse-Green et al. 2012).

A number of single chance finds, some of uncertain or dubious provenance, make up much of the rest of the evidence for a lower Paleolithic presence in Wales. Among these are single bifaces from reliable provenances from Afon Marlais, Narberth, Pembrokeshire (Green and Walker 1991: 30–31; Walker 2016), and Rhossili, Gower, Swansea (Fig. 2; Green 1981). The number of such finds is, however, small, and sites tend to be single spots where chance losses have been made. These do not provide reliable evidence for their dating but hint at what must have been a more extensive hominin presence in Wales than the single, well-excavated site of Pontnewydd Cave might suggest.

A true Neanderthal presence in Wales is indicated by finds made in excavations at just a small number of sites. The oldest of these is Coygan Cave, a site excavated at various times in the nineteenth and twentieth centuries. The site mainly contained a hyena den assemblage with a middle Last Glacial fauna among which are the heavily gnawed remains of *Mammuthus primigenius*, *Coelodonta antiquitatis*, *Rangifer tarandus*, *Bison priscus*, and *Ursus arctos* (Aldhouse-Green et al. 1995). As well as hyena occupants, a human use of the cave is hinted at through the discovery of three *bout coupé* bifaces and three worked flakes. Two of these bifaces were seemingly cached, having been carefully left together beside the cave wall (Fig. 3). Perhaps it was the Neanderthal's intention to return to the cave to make future use of the tools (White and Jacobi 2002). The dating of the Neanderthal presence at Coygan is currently thought to lie between 66,000 and 38,000 BP, based on redating of associated faunal material by the late Roger Jacobi (*pers. comm.*).

Levallois flakes were discovered during the excavations ahead of the construction of the Second Severn Crossing at Sudbrook, Monmouthshire (Green 1989: 194–196). These also imply a Neanderthal presence in Wales; unfortunately, dating the Sudbrook assemblage is not possible due to the lack of a stratigraphic context for the finds.

Paleolithic Archaeology of Wales: Overview, Fig. 3 The bifaces found at Coygan Cave, Laugharne, Carmarthenshire (© National Museum of Wales)

Further hints at a Neanderthal presence can be seen in the presence of leaf points at two Welsh cave sites: Ffynnon Beuno, Tremeirchion, Denbighshire, and Paviland Cave, Gower, Swansea (Jacobi and Higham 2010a: 186); there is also a chance find made away from the caves at Goldcliff, Monmouthshire (Walker 2015: 118–119).

The arrival of evolutionary modern humans in Wales appears to have taken place sometime around 36,000 years ago based on dated parallels from elsewhere in the UK (Jacobi and Higham 2010a: 188). There are currently just two sites known from Wales where there is an Aurignacian presence. Paviland Cave, Gower, Swansea, contained the largest assemblage (see Walker's EGA entry ▶ Paleolithic Archaeology of Wales: Paviland Cave). Here, stone tools of diagnostic Aurignacian forms were found. The second site is Hoyle's Mouth Cave, Tenby, Pembrokeshire, from where a single Aurignacian burin busqué is recorded (Green and Walker 1991: 58; Walker 2016: 7).

An early Gravettian presence is demonstrated in Wales by the rich burial of a skeleton within Paviland Cave, Gower, Swansea (also known as Goat's Hole, Fig. 4). The burial has been redated to around 29,000 radiocarbon years BP by Jacobi and Higham (2008), some 34,000 years ago (Dinnis and Stringer 2013). The skeleton, known as the "Red Lady" of Paviland Cave, is that of a young adult male who was buried carefully in a grave with perforated shells, ivory rods, and bracelets. Red ocher was present in the burial (Aldhouse-Green 2000).

Paleolithic Archaeology of Wales: Overview, Fig. 4 The exterior of Paviland Cave, Gower, Swansea (© National Museum of Wales)

A later Gravettian activity is seen by the presence of tanged blades (or font Robert points), the dating of which may be around 28,000

radiocarbon years BP, based on parallels from the site of Maisières-Canal, Belgium (Jacobi and Higham 2010a: 210). These have been found in the assemblage from Paviland Cave and also Cathole Cave, Gower, Swansea, where the context is also not recorded (Garrod 1926: 66–67).

As would be expected, there is no clear evidence for a human presence in Wales during the height of the Last Glacial, and the evidence provided by the recent work of Jacobi and Higham 2010a has pushed the departure of humans from Wales further back than dating evidence from Paviland Cave had previously indicated (Aldhouse-Green 2000). That there was a hiatus in human presence in the country is to be expected, given the proximity of the ice that covered the majority of the country, just stopping short of covering the entirety of Wales.

The new dating of bones from Sun Hole, Cheddar, Somerset, suggests that humans had returned to southern Britain by 12,600 radiocarbon years BP and reached Wales soon afterward (Jacobi and Higham 2010b). The colonization of Britain at this period is thought to be at a time when wild horses were a key part of the fauna and which were very soon joined by red deer and wild cattle. The diversity of a large game fauna may have been the factor that enabled the Wales to be resettled at this time (Jacobi and Higham 2010b: 243). Lithic artifacts from Welsh caves that indicate a human presence are Cheddar points, end scrapers, burins, piercers, and retouched truncations (Fig. 5). The *en éperon* butt preparation technique is also a distinctive indicator for tools of such age (Jacobi and Higham 2010b). In Wales, the evidence for people of this date can be found at Paviland Cave, Gower, Swansea; Worm's Head Cave, Gower, Swansea; Hoyle's Mouth Cave, Tenby, Pembrokeshire; Nanna's Cave, Caldey Island, Pembrokeshire; Cathole Cave, Gower, Swansea; and Kendrick's Cave, Llandudno, Conwy. Finds have also been recovered from a rare open-air site at Cophill Farm, Chepstow, Monmouthshire (Walker 2015). Few of these caves have been subject to full study and dating; most of the evidence available comes from the stone tools found during excavations at the sites.

Paleolithic Archaeology of Wales: Overview, Fig. 5 A Cheddar point from Nanna's Cave, Caldey Island, Pembrokeshire (© National Museum of Wales)

Final Paleolithic sites are characterized by a technology dominated by the presence of penknife points, a tool not seen among the assemblage at Gough's Cave. The dating of sites with penknife points can now be attributed to a time between 11,800 and 10,800 radiocarbon years BP (R.M. Jacobi *pers. comm*. 2005). Caves, including Priory Farm Cave, Pembroke, Pembrokeshire (Fig. 6), and Nanna's Cave and Potters Cave, Caldey Island, Pembrokeshire, all have these distinctive tools among their assemblages.

In Wales, the coldest part of the Younger Dryas started around 11,600 radiocarbon years BP and lasted until c. 10,200 or 10,000 BP based on evidence for bare, stony ground from pollen cores taken at Llyn Gwernan, Ceredigion (Lowe and Lowe 2001: 147–148). During this period, the winter sea ice margin lays just south of Strumble Head, Pembrokeshire. While much of the precipitation fell as snow, there would not have been a good snow cover on the ground because of the effect of very strong winds and the sparseness of the vegetation which prevented such cover developing (Isarin et al. 1998: 451). A consequence of this cold stadial was that people left Wales, only returning once the climate improved sufficiently to sustain life once again.

Paleolithic Archaeology of Wales: Paviland Cave

Elizabeth A. Walker
Department of History and Archaeology, Amgueddfa Cymru – National Museum Wales, Cardiff, UK

Introduction

Paviland Cave (also known as Goat's Hole), Gower, Swansea, Wales, is a cave site with a long history of occupation both before the Last Glacial Maximum and again after it. The cave is famous for the excavation by William Buckland in 1823 of the skeleton of a young adult male with associated grave goods.

Definition

Paviland Cave lies on the southern coast of Gower in South Wales. The cave has been extensively excavated many times since the first discovery of finds within it in 1822. The most recent excavations took place there in 1996. The cave has become well known for the discovery of the skeleton known as the "Red Lady" of Paviland Cave which has been the focus of interest in the site since its discovery over 200 years ago. Now dated to around 34,000 years ago, the "Red Lady" can claim to be one of the oldest burials of an evolutionary modern human anywhere to have been associated with manufactured grave goods.

Key Issues

Excavations first took place in Paviland Cave in 1822 when two Roman coins, and what were recorded as elephant bones, were discovered in the cave (Fig. 1). Early in January 1823, Professor William Buckland visited the cave in the company of Miss Talbot and John Traherne. They undertook a day digging in the cave and the following day were joined by Lewis Weston Dillwyn of Swansea,

Paleolithic Archaeology of Wales: Paviland Cave, Fig. 1 Paviland Cave, Gower, Swansea, Wales (© National Museum of Wales)

during which time they recovered the remains of a partial skeleton which they initially took to be a customs man, thought to have been overcome by smugglers on the Gower coast. On February 15, 1823, Buckland announced the findings in a public lecture given in the Ashmolean Museum, Oxford. Later the same day, Buckland wrote to Lady Mary Cole, the landowner, "the man whom we voted an exciseman, turns out to be a woman, whose history would afford ample matter for a Romance to be entitled the Red Woman or the Witch of Paviland – for some such personage she must have been" (letter from William Buckland to Lady Mary Cole dated 15th February 1823 in the collection of the Department of Natural Sciences, National Museum of Wales NMW 84.20G.D167; North 1942: 108). The interpretation offered by Buckland was that this was the burial of a woman who had lived in the cave during Roman times and was associated with the camp on the hill above the

cave (now known to be an Iron Age promontory fort). The grave goods included ivory bracelets, ivory rods, and perforated shells. The skeleton was also stained red with ocher, all of which led Buckland to infer that the skeleton was that of a female, a woman of loose morals. Buckland illustrated his description of his discoveries in the cave with a reconstruction of what the site might have been like before digging commenced within it (Fig. 2; Buckland 1823).

Since the discovery, the skeleton, now preserved in the collections of the Oxford University Museum of Natural History, has been subject to regular scrutiny and study, including direct dating on four occasions. The first date obtained by Kenneth Oakley in 1968 was of 18,460 ± 340 BP (BM-374; Powell 2000: 272) and caused some consternation, as it falls during the period when the ice would have been at its maximum during the last Glacial. Further dating was undertaken in 1989 on powder remaining from Oakley's date. This resulted in the more believable date of 26,350 ± 550 BP (OxA-1815; Powell 2000: 272). More recently, dates have been obtained on a rib fragment of 28,870 ± 180 BP and 28,400 ± 320 BP (OxA-412; OxA-16,502) and on a scapula fragment 29,490 ± 210 BP and 28,820 ± 340 BP (OxA-16,413; OxA-16,503) (Jacobi and Higham 2008: 904, Table 8). This new dating places the skeleton in the early Gravettian at a time that correlates with a period of interstadial warmth, and as a burial, it is currently among the oldest to be associated with manufactured grave goods (Jacobi and Higham 2010: 206).

Study of the skeleton by Trinkaus and Holliday (2000) concluded that the remains are that of a young adult male, aged in his mid-twenties at death. He was average in body size and generally relatively gracile for an early upper Paleolithic human (Fig. 3). The skeletal evidence shows no evidence for the cause of his death and his bones were generally very healthy. Stable isotope analysis of the "Red Lady" indicates a diet that had some marine content of around 10%. The suggestion is that the individual was highly mobile and that marine foods were exploited opportunistically during his annual movement around the

landscape, as opposed to indicating seasonal mobility between inland and coastal zones (Richards 2000). DNA analysis shows the "Red Lady" to match the most common sequence found in modern humans (Sykes 2000: 77).

The grave goods found and associated with the "Red Lady" burial include perforated shell beads of flat winkle, *Littorina littoralis*, of which Buckland recorded finding about "two handfuls" close to the part of the thigh bone where the pocket is usually worn. These may have been worn as beads or sewn onto clothing. The shells would have been available along the contemporary coastline (Aldhouse-Green 2000: 115). Ivory rods and bracelets were also found in the burial. Whether the rods were unused blanks for beads or, as Aldhouse-Green favors, as fragments of magical wands remain unclear. The bracelets are small in size and have been reinterpreted as possible talismans that were hung from clothing rather than for wearing on the wrist (Jacobi and Higham 2010: 204). The red staining of the bones, which has given the "Red Lady" his sobriquet, has been demonstrated to come from ocher, originating from locally obtained hematite that was deliberately emplaced within the grave. How the ocher came to be present remains unclear. The more probable of the theories include the possibilities that it was associated with preservation treatment of clothing or that it was sprinkled over the body in the grave. Parallels for the use of ocher in rich Gravettian burials can be found elsewhere in Europe, and so this is not uncommon (Aldhouse-Green 2000: 239).

Paviland Cave, while often best known for the remains of the "Red Lady," also contained archaeological evidence of other occupations both within the pre- and post-last Glacial periods. Evidence for this comes mainly from the lithic artifacts, which have been subject to study by a number of researchers in recent years. The lithic finds were mainly recovered from excavations which took place in the cave in 1912 by Professor William Sollas. His excavations recovered over 4000 lithic artifacts which today are split between the collections of the National Museum of Wales and the Ashmolean Museum, Oxford (Swainston and Brookes 2000: 31). Analysis of these collections has resulted in various interpretations. The most recent interpretation by Jacobi and Higham (2010: 215–216) suggest that there was a possible very late Neanderthal presence at the site evidenced by nine leaf points in the assemblage (Swainston 2000: 100). Dating at Paviland is hampered by the palimpsest nature of the assemblage, so dating of specific events is dependent on parallels drawn from other UK sites. For blade leaf points, Jacobi and Higham have drawn on the date from Badger Hole, Wookey Hole, Somerset, where a fragment of horse dentary bone, associated with a leaf point, provides a date of 36,000 ± 450 BP (OxA-11,963; Jacobi and Higham 2010: 188). Other dates from hyena dentary fragments from Bench Quarry Tunnel, Brixham, Devon, and from Pin Hole, Creswell Crags, Derbyshire, are slightly older. However, Dinnis and Stringer suggest that this interpretation may be too simplistic. They leave the answer to their question who made the Paviland blade leaf-points open as to whether it was a late Neanderthal or an early modern human (Dinnis and Stringer 2013: 105).

An evolved Aurignacian presence is indicated by a number of key tool forms in the assemblage including burin busqués and what is being termed the "Paviland burin" (Dinnis 2009). Dating of the Aurignacian occupation event is by association with dating for worked antler/bone points from Uphill Quarry, North Somerset; hyena den, Wookey Hole, Somerset; and Pin Hole, Creswell Crags, Derbyshire, all of which fall around 32,000 radiocarbon years BP (Jacobi and Higham 2010: 195). The burial of the "Red Lady" at around 29,000 radiocarbon years BP is a single event that took place in the very early Gravettian period. This was followed by a slightly later use demonstrated by the presence of tanged blades the dating of which may be around 28,000 radiocarbon years BP, based on parallels from the well-dated site of Maisières-Canal, Belgium (Swainston 2000: 108; Jacobi and Higham 2010: 210). A post-last Glacial lithic assemblage includes diagnostic tool forms such as backed blades, Cheddar points, a Creswell point, and a penknife point (Swainston 2000: 108–109). These might suggest a use of the site between around 12,600 BP and 11,600 radiocarbon years BP.

As well as the lithic artifacts, many large mammal bones were recovered during the excavations at the cave. These are also difficult to date with any certainty other than by direct dating through AMS radiocarbon techniques. The Aldhouse-Green report resulted in some 46 dates being generated on species including *Cervus elaphus*, *Ursus arctos*, *Crocuta crocuta*, *Rangifer tarandus*, *Mammuthus primigenius*, *Canis lupus*, *Equus ferus*, *Coelodonta antiquitatis*, *Bison priscus*, and *Megaloceros giganteus* (Pettitt 2000: 64). Several of these dates have now been questioned, following the introduction of ultrafiltration for dating samples, so while it is possible to say with certainty that bones of these species have been found within the deposits of Paviland Cave, their dating is considered to be less accurate than was the case at the time of their publication in 2000 (Jacobi and Higham 2010: 172).

Paviland Cave is therefore demonstrated to be one of the most significant sites of Paleolithic age in Wales. It has the longest recorded sequence of events, which can be elucidated from the lithic and dating records. The discovery of what remains the only formal burial of Gravettian age from the UK also adds to the importance of the discoveries made at this site.

Paleolithic Archaeology of Wales: Pontnewydd Cave

Elizabeth A. Walker
Department of History and Archaeology, Amgueddfa Cymru – National Museum Wales, Cardiff, UK

Introduction

Pontnewydd Cave, Denbighshire, Wales, contains a unique early Neanderthal site on the northwesternmost edge of the known Paleolithic world.

This cave site is unusual having survived in an area that has experienced a series of glaciations since early hominins made use of the cave 225,000 years ago. As such it makes a significant addition to the limited number of fossil hominin remains so far discovered in the United Kingdom.

Definition

Evolutionary early Neanderthal fossils, associated stone tools, and a contemporary faunal assemblage have all been excavated from deposits within Pontnewydd Cave. Dating back to around 225,000 BP during marine isotope stage 7 (MIS 7), the deposits are not in situ but washed into the cave during debris or mudflows.

Key Issues

Pontnewydd Cave in the Elwy Valley in Denbighshire, northeast Wales, provides evidence for the earliest hominin occupation of Wales. The cave was first mentioned by Reverend Edward Stanley in 1832 who described visiting it when the road was being constructed that today runs downhill from Cefn Meiriadog to Bont Newydd in the valley bottom (Stanley 1832: 42). Stanley described the cave as having great potential, as it was entirely blocked up with soil which might contain important new organic remains. William Boyd Dawkins, Mrs. Williams Wynn, and the Reverend D. R. Thomas, Vicar of Cefn, are the first people recorded to have investigated Pontnewydd Cave at a date sometime prior to 1874. The exact dates and the extent of their excavations are not recorded, but it seems these were extensive as Thomas McKenny Hughes and the Reverend Thomas, who published their own investigations of the cave in 1874, noted that the deposits had already been removed from the first 25 yards into the cave from the entrance (Hughes and Thomas 1874: 388). McKenny Hughes' work revealed a series of crude stone and flint tools, a faunal assemblage which he recorded as including *Hyaena spelaea, Ursus spelaeus, Ursus ferox, Equus caballus, Rhinoceros hemitoechus, Cervus elaphus, Capreolus capreolus, Canis lupus, Canis vulpes, Meles taxus*, and *Homo sapiens*. The human tooth was sent to George Busk for identification, and it was he who recognized it as being larger than any human tooth he had previously seen (ibid: 390). Today, this tooth is currently unlocated, although the stone tools survive in the collection of the Sedgwick Museum of Geology in Cambridge, UK.

Paleolithic Archaeology of Wales: Pontnewydd Cave, Fig. 1 Pontnewydd Cave, Denbighshire, Wales (© National Museum of Wales)

The cave was largely left untouched until 1940 when it was requisitioned for wartime use as a store for land mines and depth charges, during which time the floor was leveled and covered with gravel over which duckboards were placed. Spoil from this work was placed outside the cave entrance, and the entrance was faced with limestone blocks to camouflage it against possible enemy attack (Fig. 1; Green 1984: 19).

In 1978, Stephen Aldhouse-Green, then working for the National Museum of Wales, commenced a research project at Pontnewydd Cave that was to last until 1995 involving some 14 seasons of excavation. An interim report was published in 1984 (Green 1984), and a final monograph of his project published in 2012 (Aldhouse-Green et al. 2012). This work has led to the discovery of some significant new observations at this cave.

The stratigraphic sequence within the cave comprises a lower sands and gravel deposit derived from glacial sediments and brought into the cave in debris flow events. This is overlain by an upper sands and gravel deposit of the same origin. An intermediate complex suggests a temperate stage when soils provided organic matter and stalagmite growth could take place. These sediments contain limestone debris as well as animal bones, some hominin fossils, and stone tools. The overlying lower breccia was formed by a major debris flow event entering the cave which caused disruption to underlying deposits and contained a higher limestone component from the vicinity of the cave. Overlying this was a stalagmite floor with water-lain silt beds formed by water pooling within the cave. A further debris flow event emplaced the upper breccia during MIS 3. This event channeled the lower breccia and intervening deposits reworking them into this deposit. A red cave earth and upper clays and sands overlie the upper breccia, neither containing any archaeological material (Fig. 2). In 1987, a second entrance was uncovered on the hillside outside the cave. This was excavated in order to record the stratigraphic sequence and was found to be approximately 5 m deep. The sequence of deposits has been correlated with those excavated from within the cave and the lower contexts also generated a similar suite of stone tools, animal bones, and one hominin tooth.

One of the first discoveries to be made during recent excavations at the cave in 1980 was a hominin tooth, PN1, a left upper second molar which displays characteristic features of taurodontism (an enlarged pulp cavity and coalesced roots) (Fig. 3). Study of this tooth led to the assertion that Pontnewydd Cave had been used by early Neanderthals (Green 1981). Further hominin finds discovered at the cave have resulted in a total of 16 teeth and 1 tooth fragment confirmed as early Neanderthal in origin (a further metapodial PN14, vertebra PN3, mandible PN2, and a lower right second molar PN8 are now believed to be of Holocene date, due to direct

dating, or originating from disturbed contexts (Aldhouse-Green et al. 1996)). Recent study of the Neanderthal fossil hominins suggests that they represent a minimum of five individuals comprising an 8.5-year-old male, a 9-year-old female, an 11–11.5-year-old male, a young adult male (14–16 years), and a mature adult male. The maximum possible number of individuals represented is 16: 9 juveniles/adolescents and 7 adults. The teeth are predominantly single teeth and mostly have crowns; although a few teeth have roots, many do not. Two teeth are still in position in a right maxillary fragment. These are the remains of the 8.5-year-old male. What is particularly interesting about this individual is that the maxilla contains a heavily worn upper fourth deciduous premolar and a lightly worn upper first molar (Fig. 4). Comparisons have been made with other well-excavated and well-studied early Neanderthal populations from elsewhere in Europe. The sites of Krapina, Croatia, and the Sima de los Huesos (SH) site at Atapuerca, Spain, have some of the closest parallels to the Pontnewydd Cave teeth. Detailed study has been undertaken of the many different dental traits and their comparisons across these and other assemblages of similar and different ages in work done by Compton and Stringer (2012).

As well as hominin fossils, the excavations at Pontnewydd Cave generated a substantial stone tool assemblage. Some 1284 stone tools were recovered and study of the character and taphonomy of the artifact assemblage suggests that the main hominin occupation took place just outside the modern cave system. The raw materials used to make the tools are predominantly hard volcanic rocks with just a small number of flint. The dominant raw materials are ignimbrite and rhyolite as well as a variety of volcanic tuffs. The resulting stone tools are consequently very crude in appearance, the nonconchoidal fracturing of such rocks resulting in laminar fractures and irregular forms. The majority of the raw materials used was available locally and need not have been transported far. Many different debris flow movements have moved artifacts from their original sites of deposition. The assemblage is technologically very consistent and may represent a single extended phase of occupation, or possibly a palimpsest of short occupations. Tool forms include Acheulian bifaces as well as a Levallois technology of prepared cores, flakes, and blades. Retouched tools include

Paleolithic Archaeology of Wales: Pontnewydd Cave, Fig. 5 Stone tools discovered during excavations at Pontnewydd Cave (© National Museum of Wales)

scrapers, knives, and denticulates (Fig. 5). There is no human occupation associated with the MIS 3 fauna in the upper breccia debris flow event.

The faunal assemblage from Pontnewydd Cave has been studied by Andrew Currant formerly of the Natural History Museum, London. The species list for the MIS 7 contexts comprises *Canis lupus, Ursus* sp., *Panthera pardus, Panthera leo, Equus* sp., *Stephanorhinus kirchbergensis, Stephanorhinus hemitoechus, Cervus elaphus, Castor fiber, Arvicola cantiana, Arvicola* sp., *Microtus gregalis*, and birds. The MIS 3 context species list comprises: *Canis lupus, Vulpes vulpes, Ursus arctos, Equus ferus, Rangifer tarandus, Ovibos moschatus, Dicrostonyx torquatus*, and *Lepus timidus*. The assemblage from the intermediate complex and the lower breccia are deemed to be of MIS 7 age with a later MIS 3 faunal accumulation from the upper breccia.

The final report, published in 2012, draws together the information gleaned by these studies and puts them into full context.

The Paleolithic in Hungary

György Lengyel
Institute of Systematics and Evolution of Animals, Polish Academy of Sciences, Kraków, Poland

Introduction/Historical Background

Systematic Paleolithic research in Hungary began at the end of the nineteenth century when three bifacial knapped lithic tools were found in Miskolc (northeast Hungary) during building the house of János Bársony (prosecutor of Miskolc) on the right bank of the Szinva Creek in the center of the town. Due to their shapes, Ottó Herman (1835–1914, ornithologist, arachnologist, ichthyologist, ethnographic, and also a politician), the polyhistor of Miskolc, classified the three finds as Paleolithic handaxes, similar to those found in the Somme River terraces in France. Critics doubted the Pleistocene origin of the finds and Herman's claim that humans lived in Hungary during the

Paleolithic. To find solid evidence for the existence of Paleolithic human population in Hungary, Herman took advantage of his political connections in Ignác Darányi (1849–1927), minister of agriculture, who encouraged the Royal Geological Institute of Hungary to launch excavations in the karstic caves of the Bükk Mountains in 1906. This action aimed at finding remains of Palaeolithic human cultures in Pleistocene geological depositional environment. The only person at the Royal Geological Institute of Hungary with an interest in cave excavations was Ottokár Kadić (1876–1957), born to a Hungarian–Croatian family. Kadić graduated as a zoologist specialized in insect anatomy, but also had interest in paleontology and prehistory. The latter field increasingly occupied his scientific interest since he reported upon of the discoveries of Neanderthal remains at Krapina Cave in Croatia in 1899. The first successful excavation in the Bükk Mountains which unearthed lithic tools from within Pleistocene layers was carried out at Szeleta Cave between 1906 and 1913 (Fig. 1). Kadić found the first bifacial laurel leaf point together with cave bear remains in 1907. The Pleistocene age of the assemblage became internationally accepted in 1911 at a paleoanthropological conference held in Tübingen, Germany. After the breakthrough of the Szeleta finds into the international research, Kadić excavated further caves in the Bükk Mountains: Peskő (1912–1942), Büdöspest (1913–1927), Herman Ottó

(1915–1916), and Subalyuk (1932). Jenő Hillebrand (1884–1950), anthropologist, the head of the archaeological division at the Hungarian National Museum, joined Kadić at the Szeleta excavations and then started his own researches in Bükk Mountains at Balla Cave (1909–1913) and Istállóskő Cave (1912–1917), Jankovich Cave (1913–1925), and Kiskevély Cave (1912–1914) in Transdanubia and Dzeravá skala (back then Pálffy Cave) in western Slovakia in the Lesser Carpathians. Further pioneers in Palaeolithic research in Hungary who conducted excavation before World War II (WWII) were Tivadar Kormos (Tata, Pilisszántó I Rockshelter), Andor Saád (Diósgyőr-Tapolca Cave, Szeleta Cave, Istállóskő Cave), Géza Megay (Görömböly-Tapolca Cave), István Gaál (Szelim Cave), and Sándor Gallus (Ságvár). The common in all the researchers active before WWII is that they were self-trained archeologists.

Definition

Lower Paleolithic

The only reliably dated Lower Palaeolithic site of Hungary is located in Vértesszőlős, western Hungary. The human occupations were found in a travertine quarry and the formation of the rock dates back to the Middle Pleistocene. Today the site is located in the open-air exhibition area of the Hungarian National Museum. László Vértes (1914–1968) excavated the site between 1963 and 1968 (Kretzoi and Dobosi 1990) and recovered four loci (sites) within the quarry out of which site I and III were the most abundant in settlement remains. Site I embedded four archaeological layers and site III did five. In the section of site I, layer 3 was covered by loess and layer 4 situated on top of the loess. Besides the archaeological remains, the travertine beds preserved an important set of Middle Pleistocene vegetal imprints and animal footprints. The most important archaeological assemblage from the site, however, consists of five fragments of teeth of a young individual and an occipital bone of an adult nicknamed Sámuel /ʃa:muɛl/. Four teeth fragments were found at site I in layer 1 and the fifth fragment among travertine debris collected from the vicinity of the finding area of the other four fragments. The occipital bone lay eight meters outside of site 1 within the travertine. According to the anatomical features, the occipital bone belongs to a *Homo heidelbergensis* that bore already some characters of the Neanderthals (Kretzoi and Dobosi 1990). The area of the site seems to have been favored by herbivores due to vegetal resources and access to water, and therefore, carnivores and humans could have been attracted by the visits of herbivores. The large mammal remains (bison, horse, rhino, deer) in the archaeological layers were found severely smashed. However, the accumulation of the bones could have only partially been related with human activity. Natural processes were also active in the formation of the archaeological record (Kretzoi and Dobosi 1990). Besides the traces of on bone breakage, the lithic artifacts and burnt bone heaps interpreted as hearths are also clear evidences of human settlements. The human occupations were dated to between ca. 200 and 350 kya with U-Th series (Kretzoi and Dobosi 1990). Recently, the travertine that included the human occipital bone was dated to 315 kya and the earliest cultural layer to 328 kya (Kele et al. 2016). According to the sedimentation in site I, the human occupation started in the OIS 9 warm period and ran into the cold OIS 8. The lithic artifacts were made of small pebbles of radiolarite and quartzite; thus, the toolkit is on average, small ca. 3 cm. Frequent types are choppers, chopping tools, notched and denticulated tools (often pointed), and scrapers. Vértesszőlős hominins utilized a similar pebble technology to the Middle Palaeolithic Neanderthals dated to the OIS 5 at the nearby Tata (Borel et al. 2017). This sliced pebbles to obtain blanks with cortical surfaces and removed flakes in a manner similar to discoid and half discoid debitage. Also, angular fragments were obtained by bipolar flaking.

Middle Palaeolithic

Middle Palaeolithic (MP) sites in Hungary can be divided into three broad cultures: Mousterian, Taubachian, and a bifacial MP.

The Mousterian has two archaeological manifestations: the typical Mousterian and the Quina

type Mousterian. The only site where both types were found in superposition is Subalyuk Cave, Bükk Mountains. The typical Mousterian was recovered from layers 1–7 and the Quina Mousterian from layers 8–14 (Mester and Patou-Mathis 2016; N.B. the numbering of the layers is ordered from bottom to top). Tentatively, layers 1–3 can be dated on the basis of the fauna to OIS 5e, layer 4 to OIS 5b, layers 5–6 to OIS 5a, layers 7–13 to OIS 4, and layer 14 to OIS 3. Zooarchaeological studies illustrated that the cave was periodically used as a den for wolves, hyenas, and cave bears (Mester and Patou-Mathis 2016). Humans occupied the cave rarely but when used, it was occupied seasonally and most archaeological remains were formed during ephemeral visits related to hunting. The typical Mousterian assemblages are accompanied by alpine ibex, chamois, red deer, aurochs, horse, and woolly rhinoceros. The lithic assemblage of the typical Mousterian employed Levallois technology, but flakes were also made using the discoidal method. The toolkit is composed of sidescrapers and Mousterian points and the blanks of the tools are often elongated.

The Quina Mousterian assemblages at Subalyuk Cave are accompanied by the same spectra of herbivores. The lithic tools were mostly made by the discoid and Quina methods, but remnants of Levallois technology were also found. Accordingly, many of the tools were made on thick, wide flakes. Quina type sidescrapers dominate these assemblages. Remarkable finds of the Quina Mousterian are the skeletal remains of two individuals of Neanderthals, an adult female and an infant (Tillier et al. 2006). The adult is represented by the mandible, a few vertebral fragments (atlas in three parts, three bodies, one spine process of a thoracic vertebra), the *manubrium sterni*, the sacrum, the left patella, fragments of a left second metacarpal and left proximal phalanx, the complete right second and left fourth metatarsal and a fragment of right third metatarsal. Compared to western European remains, the Subalyuk Neanderthal adult is less robust. One modern-like feature of the skeleton is the presence of an *incurvatio mandibulae anterior* (Tillier et al. 2006). The juvenile skeletal remains are represented by a cranium with two maxilla and the left nasal bone. Analyses of the human bone deposition supposed that the child was buried and the adult body lay on the cave floor uncovered (Mester and Patou-Mathis 2016).

Further typical Mousterian finds from Hungary are sporadic, but more abundant evidences were found for Quina Mousterian occupations. The largest site after Subalyuk Cave was found at Érd in the Transdanubia, western Hungary, excavated by Veronika Gábori-Csánk (1929–1996) (Mester and Moncel 2006). The site is found in open-air embedded in loess. The human occupations originally were interpreted as a cave bear hunting camps, and zooarchaeological analyses revealed that the site alternatively was occupied by denning cave bears, hyaenas, and humans (Daschek 2015). Besides the wealth of cave bear bones, archaeological remains are knapped quartzite tools made of pebbles. The archaeological finds are found in six levels embedded within three stratigraphic units. The flakes were produced with semi-discoid, discoid, and Quina methods; the tools are most frequently sidescrapers. Two levels were dated with the decay counting radiocarbon method on charcoals, but the dates 35 ka and 44 ka uncal BP seem young compared to the age estimated on the basis of the stratigraphy to the Lower Pleniglacial period ca 60 ka.

The largest site of Taubachian in Hungary is Tata (Borel et al. 2017). Tata, similarly to Vértesszőlős, was also found intercalated by travertine beds. Tata has been excavated since the early twentieth century to present through several campaigns. The fauna consisted mostly of mammoth and horse remains and a remarkable find is a mammoth tooth plate polished and stained with red ochre. The travertine beds delimiting the archaeological layer were dated to 116 kya 3 m below and 76 kya 1 m above with U-Th series; therefore, the archaeological layer is of Early Weichselian age. With this dating, this is the only reliably radiometrically dated MP site in Hungary. The lithic tools were made of small radiolarite pebbles giving the industry a microlithic character. The cores were exploited from two or more striking platforms, and several items showed similarity to discoid and half discoid

method. The technological root of the Taubachian industry was found in the Lower Palaeolithic, for instance, Vértesszőlős site dated to MIS 9. Frequent tool types are sidescrapers, offset points, denticulated flakes, and notches. Bifacial retouching also occurs on a few tools.

The third type of MP human culture produced bifacially shaped lithic tools. Out of the bifacial MP cultures, the earliest could be the Jankovichian. The culture received its name from Jankovich Cave in the Transdanubian Range, Gerecse Mountains. Gábori-Csánk (1993) pointed out that the bifacial tools were similar to those found in the late MP Central European bifacial leaf point industries, today called Micoquian. A striking character of the Jankovichian culture is the bifacial leaf-shaped tool and the presence of Levallois technology. At Remete-Felső Cave, Jankovichian tools were found associated with two incisors and a canine of *Homo*, which do not have distinct features of either Neanderthals or modern humans (Tillier et al. 2006).

Another bifacial phenomenon in the Hungarian MP is called the Bábonyian. Several open-air sites have been found along the eastern margin of the Bükk Mountains though the only excavated one is at the eponymous site in the village of Sajóbábony (Ringer and Adams 2000). The Bábonyian also was defined as a variant of the Central European Micoquian (Ringer 1983). To date, the chronological position of this industry is insecure due to the lack of absolute dating and reliable stratigraphy. Bábonyian lithic tool types are MP type scrapers, bifacial knives, bifacial leaf points, small hand axes, and rarely sturdy blade tools of Upper Palaeolithic (UP) types such as the endscraper. Open-air sites with bifacial tools and solely MP tool types were also recorded from the western half of the North Hungarian Range, but absolute dating has yet to be performed (Markó 2008–2009).

Middle to Upper Palaeolithic Transition

The beginning of the UP in Hungary long has been related with the Szeletian, which is often classified as an MP–UP transitional industry due to that it contains bifacial leaf points, leaf-shaped bifacial scrapers, endscrapers, UP tools made of blades, and retouched and notched flakes (Mester 2014). The eponymous site, Szeleta Cave, located in northeastern Hungary, today is considered inappropriate to represent what the Szeletian is. The main reason is the weak archaeological integrity of most layers that seem to have been reworked by geogenic and biological agents (Lengyel and Mester 2008). Originally, the Szeletian was divided into two phases, the Early and Upper, and Szeleta Cave was the only site in Central Europe to reveal the two phases in superposition. While the dating of the Upper Szeletian layers at Szeleta Cave is insecure (Lengyel and Mester 2008), the Early Szeletian layers at Szeleta Cave were dated to between 46 and 36 ka uncal BP (Hauck et al. 2016).

Upper Paleolithic

The earliest UP archaeological entity in Hungary is the Aurignacian. The first site recovered in Hungary was Istállóskő Cave, Bükk Mountains. Excavations in the 1910s by Jenő Hillebrand unearthed the first lithics and after several campaigns of others (O. Kadić, M. Mottl and A. Saád) László Vértes recovered between 1947 and 1951 the two-fold cultural succession what today is widely known from the site (Vértes 1955). Thus, the archaeological sequence contained Aurignacian I (lower layer) and Aurignacian II (upper layer) occupations. The lower layer yielded about a hundred osseous tools complete and fragmented and a few lithic remains. The split base osseous point was the prime character of this assemblage. In the upper layer, the number of osseous tools dwindled, but the lithics were more numerous. Mladeč points (a broad-based point) characterized this osseous industry. Also, a modern human child tooth (permanent molar) was found in the upper layer by Vértes (Tillier et al. 2006). Direct radiocarbon dates obtained from two antler points (not split-based type) from the lower layer ca 35–33 ka uncal BP (Davies and Hedges 2008–2009) also confirm the Aurignacian chronological position. The upper layer radiocarbon dates 28–30 ka uncal BP on charcoals (Davies and Hedges 2008–2009) are similar to those obtained from

sites yielding broad-based bone points in Moravia, Czech Republic (Wild et al. 2006) and Slovenia (Moreau et al. 2015). Most lithics from the two layers of Vértes are general types such as retouched blades and flakes, end-scrapers, and burins, except a very few bifacially shaped tool fragments, and some backed bladelets in the upper layer (Markó 2015). The presence of bifacially shaped tools was often interpreted as a Szeletian intrusion (Vértes 1955), but the backed bladelets clearly signify a Gravettian occupation at Istállóskő (Markó 2015). The pre-Vértes material, which is merged into the upper layer today (Markó 2015), nevertheless, was attributed to the end of the Middle Aurignacian or Upper Aurignacian by the taxonomy of the 1930s, which is today equivalent of the Gravettian. Besides the dominating cave bear, the fauna of the lower layer consist of chamois, reindeer, ibex, and bison (Vörös 2003–2004). The upper layer shows a similar spectrum of animals with the addition of elk (Patou-Mathis et al. 2016).

Another dated Early Upper Paleolithic site in Hungary is Peskő Cave near Istállóskő. Peskő is also classified among the Aurignacian sites in Hungary, and by 14C dates 33.5–38.3 ka uncal BP obtained from osseous artifacts, this could be the oldest one (Davies and Hedges 2008–2009). However, typologically the osseous tool assemblage is rather undiagnostic, so are the lithic tools that are general UP types lacking any attribute of Aurignacian (Mottl 1942).

The directly dated earliest modern human remain in Hungary that may have belonged to the Aurignacian population was found at Görömböly-Tapolca Cave in Bükk Mountains by G. Megay. The human remain is an occipital bone (Tillier et al. 2006) dated to 30.3 ka uncal BP (Davies and Hedges 2008–2009). The small lithic assemblage recovered together with the occipital bone is typologically undiagnostic; therefore, the cultural affiliation of the site remained unclear.

Characteristic Aurignacian lithic assemblages were reported only from open-air sites yet unexcavated in eastern Hungary, for instance, Nagyréde near Mátra Mountains (Chu 2018; Chu et al. 2018; Lengyel et al. 2006). Typologically, the carinated endscraper, nosed endscraper, carinated burin, busked burin, and retouched blades are clear characters of the Aurignacian.

The Middle UP (MUP) archaeological record in Hungary begins with the Gravettian. The earliest Gravettian occupations were claimed to be as old as 28–26 ka uncal BP and classified Pavlovian or Old Blade Gravettian (Dobosi 2009). The Pavlovian was described as a blade technology that produced mostly burins, end-scrapers, and retouched blades. Backed blades and bladelets and Gravette/microgravette points compose the minority of the tools. Mammal species from the sites were the reindeer, elk, mammoth, and horse. A prominent site from this period is Bodrogkeresztúr in north eastern Hungary.

The Late UP (LUP) period is coeval with the Last Glacial Maximum (LGM) and the subsequent deglaciation period between 21 and 12 ka uncal BP (Dobosi 2009). The human settlements belong to the Ságvárian and Epigravettian cultures. People of both cultures hunted reindeer and horse.

A widely known LGM site in Hungary is Ságvár (the eponym for Ságvárian) where Miklós Gábori (1925–1996) recovered remains of two huts. The Ságvárian culture dated to between 20 and 17 ka uncal BP was characterized by the use of fine grained radiolarite pebbles to obtain UP type tools; therefore, a synonym for the Ságvárian was the Pebble Gravettian. The tool types are similar to those found in the Pavlovian, including the backed bladelets. The Epigravettian was defined in Hungary as a descendant of the Gravettian on the basis of the blade technology and the lack of pebble processing in lithic technology (Dobosi 2009). Opposed to the Ságvárian, Epigravettian sites were dated to the end of the LGM and to the whole post-LGM period until the terminal Pleistocene. The Epigravettian 18 and 12 ka BP was divided into two phases (Dobosi 2009): expedient lithic industries between 18 and 16 ka BP, for example, the site of Jászfelsőszentgyörgy, and backed bladelet dominated industry between 16 and 12 ka BP after Esztergom-Gyurgyalag site. Both Epigravettian phases lack the pebble raw material use and the tool types of the Pavlovian characterized the Epigravettian. A frequently used synonym for the Epigravettian is the Young Blade Gravettian.

During the terminal UP period, Hungary seems to have been rarely populated because the only site is Lovas near Lake Balaton (Sajó et al. 2015). Lovas, dated to ca 11.5–12.0 ka uncal BP, was a mineral dyes extraction site that preserved several mining tools made of elk bone. Since the lithic tools are undiagnostic, it is insecure to culturally classify the site.

Key Issues/Current Debates

Many of the key Paleolithic cave sites of Hungary were excavated in the first half of the twentieth century often without producing useful documentation. Also, the large portion of the sediments were removed at these sites and no complete stratigraphic sequences are available to study today. This issue greatly supports debates over the interpretation of their archeological assemblages.

Emerged from this situation, an intensive debate was formulated over Jankovich Cave. The assemblage has a dual character. On the one hand, it contains bifacial leaf tools which match the Late MP (LMP) chronological position and, on the other hand, there is an osseous point component of the assemblage, which generally is related with EUP. These two components of the archaeological record were recently claimed to have been formed together by LMP Neanderthal technology (Markó 2013).

The Jankovich case further touches upon the interpretation of the Istállóskő Cave Aurignacian occupations, where the lithic industries of both layers lack Aurignacian character. Due to the absence of Aurignacian lithic tool types, Markó (2015) found no evidence to classify the lower layer as Aurignacian and instead suspected a similarity with Jankovich Cave's LMP assemblage containing both bifacial leaf tools and osseous points. Opposed to this, Patou-Mathis et al. (2016) claimed Istállóskő Cave lower layer is Early Aurignacian since split base points were never found associated at sites having good archeological integrity with cultures other than Aurignacian. The zooarchaeology study by Patou-Mathis et al. (2016) emphasized that the osseous hunting weaponry and the lack of diagnostic Aurignacian lithic tools refer to differences in site function between caves and open-air sites of Aurignacian in Hungary. Istállóskő Cave upper layer, according to Patou-Mathis et al. (2016), is most likely also Aurignacian, based on those few diagnostic artifacts, while Markó (2016) claimed this is the only well-dated assemblage where leaf shaped tools and Gravettian artifacts were found together.

After several revisions on the archeological sequence at Szeleta Cave, the eponymous site of the Szeletian culture still seems to be inappropriate to represent what Szeletian is. Most likely, the Early Szeletian at Szeleta Cave (layers 3–4) represent the Szeletian of Central Europe (Mester 2014). But, due to the presence of other cultural remains interstratified such as Aurignacian and Gravettian, also to dating anomalies (Lengyel and Mester 2008; Markó 2016), the assemblages of layers 3 and 4 are most likely impure for technological considerations. The bifacial leaf point collection of the Szeleta Cave layers 3–4 was found similar with Jankovich Cave bifacials and therefore there might be a possibility that the Szeletian is an LMP industry (Mester 2017). The Upper Szeletian assemblages (layers 5–6), which contain backed bladelets and Gravette/microgravette points were classified as an industry contemporaneous with the Late Gravettian directly preceding the Last Glacial Maximum (Lengyel et al. 2016). Concerning the putative chronological position of these layers, Markó (2016) found no reason to date these artifacts to the Late Gravettian.

Another debate goes on over the classification of the MUP and LUP in Hungary. The latest research on the lithic assemblages from the period between 28 and 12 ka uncal BP proposed that the first Gravettian settlements can be dated to the Late Gravettian period 25-21 ka uncal BP on the ground of typological similarities with dated sites in Slovakia, Poland, Czech Republic, and Austria (Lengyel 2016). Main arguments for a new taxonomy were the lack of Pavlovian artifacts in the assemblages called Pavlovian and the low integrity of the radiocarbon dating results which did not

support the claimed chronological position of the Pavlovian assemblages. Concerning the LUP, Lengyel (2016) further proposed to call all LGM sites Early Epigravettian and abandon the term Ságvárian, and reclassified sites dated after the LGM under the term Late Epigravettian.

International Perspectives and Further Directions

As far as the Hungarian Paleolithic research is concerned, the number of projects and the international dissemination of the results is less intense in comparison with other countries of Europe. An important task for the Hungarian research is to enlarge the number of researches with involving wider spectrum of scientific analytical methods for maximizing the quality of the achievements. The territory of Hungary possesses only a fragment of the archaeological record of each Paleolithic hunter-gatherer society in this region. The most effective way, therefore, to study and interpret the archaeological record of Hungary is in collaborations with other countries situated on the same foraging territory of Paleolithic hunter-gatherers.

Acknowledgments This study was supported by the National Science Center (NCN), Poland decision No. DEC-2016/23/P/HS3/04034. This project has received funding from the European Union's Horizon 2020 research and innovation programme under the Marie Skłodowska-Curie grant agreement No 665778.

Paleonutrition and Bioarchaeology: Ethical Perspectives

Isabelle Ribot
Département d'Anthropologie, Université de Montréal, Montréal, QC, Canada

Introduction

The development of bioarchaeology through the study of ancient populations at large and their contextual data in particular has contributed to the emergence of many subdisciplines, for example, paleonutrition, paleopathology, paleoparasitology, paleoepidemiology, and palaeogenetics. However, key issues have often emerged from paleonutrition, as this area covers both nutrition (nutrients provided by food) and diet (food consumed by humans). These two themes are essential for bioarchaeologists who explore the evolution of human societies. When we ask about what people ate in the past, it is a way of approaching the notion of identity of a population and its adaptation to an environment through the adoption of an economic strategy. Eating behaviors (food consumption and cooking practices) are cultural characteristics that may reflect a biological identity; however, this is not always so, because culture is not simply equal to biology. Thus, paleonutritional reconstructions contribute indirectly to stimulate current ethical debates in bioarchaeology, especially when analyzing human remains that are ancestors to descendant communities today.

Definition

As a participant to a holistic and scientific approach based on the study of sites, bioarchaeology integrates various cultural (history, archaeology) and biological data (demography, health, diet, origins). Two notions are central to this approach which originates from the New Archaeology and Anthropology: that of

"population" in evolutionary terms but also that of "society." The goal is thus to attempt to reproduce both biological but also social history (way of life in the past) for a past group and to explore their relationship with their environment (Larsen 1999). The subdiscipline of paleonutrition, although focusing on past eating behaviors and their evolution through time, concerns many other aspects, including the study of ancient diseases and mortality issues (Steckel and Rose 2002). Indeed, the specific sanitary and epidemiological conditions of a group can be explained by many factors (genetic and environment) and, moreover, are not necessarily directly linked to the diet consumed. After the development of archaeological sciences and of paleoenvironmental studies, bioarchaeology and consequently paleonutrition now rely on a wide range of data, from soil to ecofacts, artifacts, and bones.

Key Issues

Firstly, major advances in paleonutrional studies are largely dependent on the type of data analyzed. Previously, these studies were mainly based on the analysis of artifacts, fauna, and plants, in order to explore diet and nutrition. Currently, all of the results already obtained have been clarified, thanks to the analysis of stable isotopes (on elements such as carbon and nitrogen) (Katzenberg 2008). Chemical analyses performed on plant and animal remains provide us with direct information on the type of food consumed during life. However, there are well-known biases in relation to various factors: climate, diagenesis, variable remodeling of the bone, and the influence of food on the marine carbon isotopic signatures. Although this approach cannot reveal the nature and quantity of nutritional intake as precisely as studies on living populations, it may suggest the main food groups consumed in the past and their position in the food chain. The analysis of stable isotopes of carbon and, in particular, the different photosynthetic modes (C_4 et C_3) observed in wild and domesticated plants allows us to identify the emergence of agriculture and imported foods in different regions of the world (corn in the Americas, millet in Europe, and sorghum in Africa). The nitrogen isotopes were also very useful to distinguish between marine and terrestrial resources in food intake. Thus, they have helped to develop interpretations of differential access to protein-rich resources and the socioeconomic stratification within a society.

Consequently, paleonutritional studies that use isotopic signatures help us to better understand the concept of identity or cultural affiliation and its evolution through time. They differ from forensic anthropology, which emphasizes the biological identity of an individual. Their approach is closely related to social archaeology, where the social dimension (position of the individual within society) is predominant. Within the goal to better understand the notion of past identity, recent research tends to combine even more methods and various data (historical records, archaeology, funerary archaeology, diet, mobility). Certain regions in the world, such as South Africa, whose peoples are differentiated by a long, diverse, and complex history, are a source of inspiration for bioarchaeological research (Cox et al. 2001; Ribot et al. 2010). With the development of agriculture, newcomers settled in areas and displaced others who were already there or they came into conflict with them. All this led to cultural and biological changes, such phenomena having occurred not necessarily in a continuous fashion in time and space. To understand these events, food reconstructions combined with other data (material culture, morphology, ancient DNA) can help us identify these past populations "in transition," exposed to various gene flows. In the case of communities of the Iron Age (AF) in KwaZulu-Natal (RAS), data on diet and morphology showed no significant change over time (Ribot et al. 2010). Thus, the hypothesis has been proposed, of a gradual assimilation of hunter-gatherers ancestral to the Khoesan, by Bantu farmers. However, elsewhere, on more recent sites associated to the period of slavery (Americas, the Caribbean, Africa), the question of identity in the broadest sense becomes a more complex concept difficult to define. Indeed, various groups of people, individuals from forced diasporas, or slaves were moved from various

regions and then intermixed with local groups, sharing with them cultural and/or biological aspects (traditions, culinary practices, languages, genes) (Larsen 1999; Cox et al. 2001).

In exploring the history of past populations as well as their identity, does paleonutrition contribute to the promotion of descendant communities as well as a recognition of their identity? The answer is positive, as a cultural affiliation can be suggested from what people eat, and thus contributes finer detail to other sources of data based on biological affiliation criteria (ancient DNA, morphology). Museums all around the world have accumulated thousands of ancestral skulls from diverse descendant communities (Native Americans, Australian Aborigines, Khoesan South Africans), often without any ethical concern. These collections were often acquired before the period of independence, while the European colonial powers dominated the world. The thinking at that time focused on the classification and definition of race. Following these events, current communities required spiritual repair and appropriate reburial of their ancestors. In the USA, the NAGPRA ("Native American Graves Protection and Repatriation Act") was established in 1990, in order to return human remains to descendant communities (Larsen 1999). Following this, a systematic process of recognition of cultural and biological identity of human remains of Native Americans has been set up and is ongoing even now in the USA, its impact even being carried out in Canada. As a result of NAGPRA legislation, bioarchaeological studies including paleonutritional analyses have multiplied exponentially, even though the scientific value of the collections are still debated and threatened by reburial (Williamson and Pfeiffer 2003). Questions of this type are also raised in South Africa in this post-apartheid era. Ethical guidelines for the management of human remains are not yet totally in place, and access to osteological collections, ancestral to current descendant communities, is more restricted than ever before (Sealy 2003).

The historic graves of slaves are sites which have recently raised a number of ethical questions, given that the descendants are often present in contemporary societies. This is, for example, the case in Cape Town, where the awareness of the collective heritage is in a process of transformation (Shepherd 2007). Debates have emerged around the complex identity of these ancient slave populations, which became more and more mixed over time. The study by Cox et al. (2001) on the skeletons found at Cobern Street, in particular, was able to reveal aspects of the life trajectory of each individual, because it combines isotopic analysis with diverse data (general history, archaeology funeral, dental changes). The level of carbon and nitrogen obtained from bones and teeth has enabled the identification of diverse groups within the cemetery, such as foreigners (consumption of C_4 plants during childhood) and natives (plants C_3). These ideas and approaches used by Cox et al. (2001) have provided a model for many other isotopic studies on slave cemeteries (Schroeder et al. 2009).

Future Directions

Recent paleonutritional studies involving food reconstructions, combined with several other approaches and advances in the area of isotopic studies, are very useful tools for researching the identity of a group. By analyzing the diet, diverse knowledge can be acquired, notably on the environment (plants, wildlife) and the period under study (economics, resource use, cultural practices). It thus brings us in a more subtle and critical way toward a better understanding of the human identity of the past and, in particular, for the groups which have been neglected throughout the past and poorly documented in historical archives. However, when human remains are discovered, the major difficulty is around ethical questions (not only in relation to reburial), which are discussed between scientists and indigenous communities. Indeed, these two groups often have in mind very different interests and priorities concerning human remains. The scientists focus on scientific merit. By contrast, some indigenous groups today lean more on the spiritual value and the memory of their ancestors or some are even very concerned about the profanation of the remains of their ancestors. These questions are

essential for our postcolonial, post-apartheid societies, and they have lead to a renaissance in the identity of indigenous populations. This process began in South Africa after 1994 (Shepherd 2007) and can be considered as a model for other countries, in particular North America, as it forces us to rethink the concepts and methods used in our very own different disciplines! For the future, it nevertheless remains to develop the inclusion of indigenous people in bioarchaeological projects, so that the acquisition of scientific knowledge can benefit these communities directly.

P

Palmer, Marilyn

Audrey Horning
Queen's University Belfast, Belfast, Northern Ireland, UK

Basic Biographical Information

Marilyn Palmer is a British industrial archaeologist and educator and a fellow of the Society of Antiquaries of London. She received her undergraduate degree in modern history from St. Anne's College Oxford in 1965 and a

postgraduate certificate of education from Leicester University in 1966. She was awarded an Oxford master of arts degree in 1969. Professor Palmer began her professional career as a history teacher at Loughborough High School and then began lecturing in history at the Loughborough College of Education. Building upon her amateur interest in industrial archaeology, she enrolled in a 4-year part-time certificate in British archaeology program at Leicester University, which she completed in 1973. Between 1977 and 1988, Marilyn Palmer was employed in the History Department of Loughborough University, rising through ranks from lecturer to senior lecturer to head of department. In 1988, she took up a post as senior lecturer at Leicester University, dividing her time equally between the History and Archaeology departments. In 1998, she moved fully into the School of Archaeological Studies, and in 2000 she was promoted to professor of industrial archaeology. From 2000 to 2006, she served as head of the School of Archaeology and Ancient History at the University of Leicester. In 2005, she received an Award of Merit from the Society for Historical Archaeology, in recognition of her many contributions to the advancement of industrial archaeology. She retired in 2008 but remains very research active.

Major Accomplishments

Marilyn Palmer's most significant achievement has been in leading the transformation of industrial archaeology from an amateur pursuit to a professional and academic discipline. She has spearheaded the integration of industrial archaeology into the broader discipline of historical archaeology, as exemplified by her founding role in the establishment of the Centre for Historical Archaeology at the University of Leicester in 2009. Her joint publications with the late Peter Neaverson (Palmer and Neaverson 1992, 1995, 1998, 2005) provided a needed methodological and theoretical dimension to the practice of industrial archaeology. Professor Palmer's research has long stressed the importance of examining the social dimensions of industrial workplaces. To that end, she has produced landmark studies examining the experiences of textile workers in South West England (e.g., Palmer and Neaverson 2005). While strongly advocating industrial archaeology as an academic pursuit, Professor Palmer has always stressed the importance of the contributions made by amateur enthusiasts in both researching and conserving industrial heritage.

Marilyn Palmer has been active in the Association for Industrial Archaeology (AIA) since its establishment in 1973, serving the organization twice as its chairperson, as joint editor for its journal *Industrial Archaeology Review*, and as honorary president. Through her AIA activities in particular, she brought together a diverse group of interested amateurs and scholars from a range of disciplines including history, archaeology, and engineering. She has also worked in an advisory capacity with the National Trust, English Heritage, and the Council for British Archaeology. She currently chairs the Buildings Archaeology Group for the Institute for Archaeologists, serves as a member of the National Trust Archaeology Panel, is vice-president and trustee for the Council for British Archaeology, and is on the English Heritage Industrial Archaeology Advisory Committee.

Marilyn Palmer's publications include both academic contributions and publications designed for the general reader. She has published on a range of industries, from lime production to iron manufacturing to lead and tin mining to the textile and hosiery industries. She has also been active in producing strategy documents as well as basic guides for interested readers. Her most influential work is *Industrial Archaeology*: *Principles and Practices* (1998), coauthored with Peter Neaverson. With David Gwyn, she coedited *Understanding the Workplace*: *A Research Framework for Industrial Archaeology in Britain* (Palmer and Gwyn 2006), a special issue of the Industrial Archaeology Review which strongly advocated taking a social approach in industrial archaeology. In so doing, it opened up new fields of enquiry and encouraged considerable discussion within and beyond the field of industrial archaeology (see Palmer 2008).

Since retiring from the University of Leicester in 2008, she has been researching the range of technological innovations adopted by country house owners from the eighteenth to early twentieth centuries. Her project, the Country House Technology Project (http://www2.le.ac.uk/departments/archaeology/research/centre-for-historical-archaeology/research-1/country-house-technology), is funded by the Leverhulme Trust.

Palmyra, Archaeology of

Jørgen Christian Meyer
Department of Archaeology, History, Cultural Studies and Religion, University of Bergen, Bergen, Norway

Introduction and Definition

In the first three centuries CE, Palmyra could be compared with the largest and most influential cities in the eastern part of the Roman Empire. It was a prosperous caravan city on the route between the Indian Ocean and the Mediterranean Sea. At the end of the third century, the legendary queen Zenobia controlled larger parts of the eastern empire, but after her fall the city was transformed to a military stronghold within a smaller area and surrounded by a new defensive wall (Fig. 1).

From 1920 to about the 1970s, the main effort of the archaeological investigations was concentrated on the Roman period up to the end of the third century within the walls of the late Roman city. The eastern part of the great colonnaded street, the tetrapylon, the temples of Bel and Baal-Shamin, the theater, and the agora with annex were cleared down to the level of the Roman period without any documentation of the later periods, and thereafter partly restored, together with the Diocletian's camp and the temple of Allath in the western part of the city (Schmidt-Colinet 1995; Delplace and Feydy 2005).

Key Issues/Current Debates/Future Research

Center of Palmyra

Since then there has been a growing awareness that the city of Palmyra covered a much larger area and that other periods need more attention. Recent investigations south of the later Roman city have revealed a large quarter with houses, an official building, and broad streets leading

Palmyra, Archaeology of, Fig. 1 Aerial view of Palmyra from the NW. (Photo J.C. Meyer)

toward the temple of Bel (al-Asʿad and Schmidt-Colinet 2006–2007) (Fig. 2). The earliest layers can be dated to the Hellenistic period, and the area was abandoned at the end of the third century CE, when the settlement was confined within the new defensive walls to the north. In the northeastern part of the city, a market has been excavated (Delplace 2006–2007), and an amphitheatre has been identified from old aerial photographs, probably from the late Roman period (Hammad 2006–2007). Excavations west and northwest of the tetrapylon have brought to light remains of several public and private buildings from the first century CE to the early Islamic period (Gawlikowski 2007) (Fig. 3). Some of the buildings were destroyed in the middle of the second century CE when the great colonnaded street was constructed, which changed the city plan of central Palmyra. Other large houses, originally for the well-to-do, were constructed in the second century CE, but in the sixth and seventh century, they were modified into several dwellings of more rural character as centers of production, probably reflecting changes in the position of Palmyra in the Byzantine era and forth (Gawlikowski 2007).

In the fifth and sixth century, three Christian churches were built north of the colonnaded street (Gawlikowski 2003; Majcherek 2009). Two of them, one with a baptistery, were still in use in the Umayyad period, but converted into habitation or a craft center in the ninth and tenth century, during the Abbasids. Another Christian basilica (Gawlikowski 1998) was probably constructed as late as the Umayyad period, and they all testify to the existence of two parallel Christian and Islamic communities in the early Islamic period. During the Umayyads the great colonnaded street was also transformed into a large market street consisting of a suq with small shops in the street between the columns (al-Asʿad and Stępniowski 1989), and a small mosque was constructed within earlier Roman buildings (Genequand 2008) (Fig. 4). The city area was finally abandoned in the ninth century, when the population of Palmyra was confined to the precinct of the temple of Bel.

The new investigations have emphasized that Palmyra had a long and very complex history. It stayed an important center also after the end of the third century, even if the habitation was confined to a smaller area within new defensive walls. It became a main garrison city of the eastern border, and later a bishopric. In the Umayyad period, when large "desert castles" or palaces were constructed in the region (Qasr al-Heir al-Sharqi and Qasr al-Heir al-Ghabi), it was still a thriving regional center with both a Christian and Islamic

population (Genequand 2008). However, the finds from the pre-Roman period are still scanty. The Hellenistic finds are few, and virtually nothing is known about the oasis in the prehistoric periods and the Iron Age. Palmyra (Tadmor) is mentioned briefly in Bronze Ages sources, but the oasis does not contain any large tell which can be compared with Ebla, Mari, or Qatna. The location of Bronze Age Palmyra is supposed to be beneath the temple of Bel. Excavations here, however, have only revealed a few shards. New stratigraphical excavations are needed in the oasis, also to clarify the extension and character of the habitation in the Roman period before the end of the third century CE. How much of the city area, which covered an area of twenty square kilometers within the farthest walls, was occupied by gardens, open spaces, and buildings? This is of great importance for any attempt to estimate the population of the city, which has ranged from 30,000 to 200,000.

The Hinterland of Palmyra

Whereas the prehistoric finds from Palmyra itself are insignificant, the finds from the hinterland north and southeast of Palmyra testify to an intensive exploitation during the PPN (Pre-Pottery Neolithic: c. 9.500–5.500 BCE), when the climate was moister and the fauna and vegetation was different (Anfinset and Meyer 2010; Morandi Bonacossi et al. 2012). The sites are located close to former fresh water lakes and wadi outlets, and they seem to be related to seasonal hunting. In addition several kites, or large hunting traps, are a common phenomenon. Unfortunately their dating is still controversial, and some of them probably belong to much later periods. The relation to the oasis of Palmyra is not clear, and it is possible that the sites are more related to the early farming communities to the north and the east. They may also be related to the early domestication of animals and the development of early pastoralism.

From the end of the Pre-Pottery Neolithic until the beginning of the early Bronze Age not much is known about the use of the steppe. In the early Bronze Age (c. 2500) at the latest, when the climate became drier, several hundred cairns were erected in the landscape (Anfinset and Meyer 2010; Morandi Bonacossi et al. 2012). Generally they are located along major tracks and mountain ridges, visible at long distances, marking the territory and the main communication lines, which is common also in other Bronze Age societies in Jordan and the Arabian Peninsula. As there are no major Bronze Age sites within the area, they probably belonged to a pastoral nomadic population, which lived in symbiosis with the agricultural societies and early cities in other parts of Syria. The exact dating of the cairns (C14 and OSL dating is awaited) and the relation to the oasis of Palmyra still need to be clarified.

In the historical period, the oasis of Palmyra with its springs could not have supported a large city with foodstuff. Palmyra needed more stable sources of nutrition within its own territory. Daniel Schlumberger was the first scholar to carry out more detailed investigations of the hinterland from 1933 to 1935. In the mountains north of Palmyra, he documented several smaller forts and 15 settlements in the tableland of Jebel Chaar, which he dated to the three first centuries CE. Most scholars have classified the settlements as pastoral holdings, as centers of stock raising, camel herding, or horse breeding.

Recent surface surveys north of Palmyra have given a much better understanding of the potential of the hinterland for production of foodstuff (Meyer 2012) (Fig. 5). Normally the area is called a desert, but it rains every year (average annual precipitation 125 mm), and it is more correct to classify it as a dry steppe. Traditional agriculture with barley is a very risky business, but by employing different kinds of water management, the fertility of the soil can be exploited. Small dams, cross-wadi walls, and cisterns with elaborate catch arm systems led the surplus water to the fields as a supplement to the annual rain. Agriculture and horticulture in semidesert areas, based on proper water management, are much more resistant to drought and minor fluctuations in the climate than their counterparts in regions with higher precipitation, and it is also known in The Negev desert, Jordan, and North Africa. The new surveys have also increased the number of known settlements dramatically in the mountain areas, which were covered by trees until recently, and have demonstrated a very dense settlement pattern, which makes more sense in connection with agriculture and horticulture, not pastoralism alone. The chronology of the sites must also be revised. Nothing can be dated to the Iron Age or the Hellenistic period, but late Roman, Byzantine, and Umayyad pottery are found in large numbers at almost all sites. This conclusion fits well with the recent excavations in Palmyra itself. The history of Palmyra did not stop after Palmyra lost its position as a major caravan city at the end of the third century. However, the chronological distribution of the surface finds cannot reveal fluctuations in the intensity of human activities at the sites. This issue can only be resolved by excavating sites with deep cultural layers. Schlumberger also investigated one of the largest dams in antiquity about 100 km southeast of Palmyra, the Harbaqa Dam near Qasr al-Heir al-Gharbi. Until recently the project has been dated to the early Roman period, later improved by the Umayyads, but some scholars now date the

construction to the Umayyad period (Genequand 2006). The site needs to be reinvestigated.

The greatest challenge for further research, apart from establishing a more precise chronology for the sites, is to correlate the settlements with the different phases in Palmyra itself and put Palmyra into a larger interregional context. We are dealing with a very long time span, covering over 800 years. Was the relationship between city and hinterland the same throughout the period and how do the later Umayyad castles fit into the picture? It has been suggested that the both the rise and fall of Palmyra and the extensive exploitation of the hinterland coincided with major climatic changes, but nothing seems to indicate that the climate of the dry steppe was markedly different from the Ottoman period or that the pre-Roman period was drier. Rather the intensive exploitation of the dry steppe seems to depend on a heavy investment in water-management systems and a high degree of political and military control. The Romans and the Umayyads were willing and able to guarantee that. Hereafter a Bedouin strategy of survival, with low degree of central control and low population density slowly took over, and Palmyra was reduced to a small oasis village in the shadow of its former greatness (Fig. 5).

Pälsi, Sakari

Oula Seitsonen
University of Helsinki, Helsinki, Finland

Basic Biographical Information

Sakari Lemmitty Pälsi (July 9, 1882–April 22, 1965) played a major role in the formation of Finnish archaeology in the early 1900s (Fig. 1).

Pälsi, Sakari, Fig. 1 Sakari Pälsi in 1932 (Photograph: Johan Emil Roine, Studio Alppila. Hannu Pälsi Collection/ Sakari Pälsi Society)

Pälsi studied in the Imperial Alexander University in Finland (now the University of Helsinki), majoring in archaeology from 1903 to 1908. He finished his Ph.D. dissertation on Finnish Stone Age in 1915, and took part in the Doctoral Promotion in 1936 to earn the title of Doctor of Philosophy. Pälsi worked all his career (1908–1946) at the Commission for Ancient Research (*Muinaistieteellinen toimikunta*; now the National Board of Antiquities) in Helsinki, and became the head of its Prehistory Department in 1938. Besides Finland and Russian Karelia, Pälsi carried out archaeological and ethnological fieldwork in Mongolia (1909), eastern Siberia (1917–1919), and Canada (1927), and traveled widely in Europe. He was one of the founding members of the Ethnological Film Ltd. (*Kansatieteellinen Filmi Oy*), in 1936, and the Peasant Culture Foundation (*Talonpoikaiskulttuurisäätiö*), in 1938.

Major Accomplishments

Sakari Pälsi was astonishingly multidisciplinary and multitalented in his research contributions. He advocated, already in his Ph.D. dissertation (Pälsi 1915), the use of ethnological (anthropological) analogies for interpreting the Stone Age remains, to acquire "both the skeleton sketched by the prehistoric studies and the muscles integrated by the ethnology" (Pälsi 1939:5). His dissertation was the second dealing with the Finnish Stone Age, and presented the first intensive landscape study in Finnish archaeology. He pioneered the use of experimental archaeology and natural scientific analyses, and used intuitive functionalism in his interpretations (Nordqvist 2017). Pälsi was especially fascinated by the "primitive technology" and the origins of art. He was also the first to suggest fishing as the main subsistence base for the Finnish Stone instead of big game, which understanding still prevails, and indeed one of the first in the world to emphasize the importance of the aquatic livelihoods in prehistory, and discussed the relativity of environmental perception (Pälsi 1916: 120, 136–137). However, some of his (mis)interpretations, for example, about the

Stone Age dwellings, continued to haunt the understandings in both Finnish and Estonian archaeology until the twenty-first century.

Pälsi started developing his photography and fieldwork skills on a seminal expedition to Mongolia in 1909 with Finnish linguist G.J. Ramstedt (Seitsonen 2017). On this archaeological, ethnological, and linguistic expedition, he became the first archaeologist to document khirigsuurs, the renowned burial monuments of the Mongolian Bronze Age, and many other archaeological remains, such as rock art. Some of the sites he documented have been visited by archaeologists again only in the 2000s. Pälsi also carried out important early anthropological and photographic documentation of the Mongolian life, and collected ethnological objects. As an example, his photographs of the Mongolian shaman Ötšir-böö have become world famous (Fig. 2). Unfortunately, the scientific manuscript from the 1909 expedition, written in German, was never published; it was rediscovered in the 1980s and published posthumously in the centennial of Pälsi's birth (Halén 1982). On the other hand, the Mongolian expedition had a strong effect on Pälsi's personal worldview and later work (Seitsonen 2017).

During his early fieldwork in the 1910s, Pälsi developed vigorously the archaeological excavation and documentation methods, for instance, different photography and mapping techniques. The precision of documentation that Pälsi achieved by the mid-1910s was reached again in Finnish archaeology only decades later. Pälsi also carried out the first bog excavations in Finland in 1914 at Antrea (Vuoksenranta) Korpilahti (nowadays Russia), uncovering the remains of one of the world's oldest known fishing nets, dated to 9140 ± 135 BP (Hela-404) (Pälsi 1920; Seitsonen et al. 2012).

Just before the outbreak of the Russian revolution in 1917 Pälsi took off on his most famous expedition, to the Chukchi and Kamchatka Peninsulas in easternmost Siberia. He was looking for anthropological analogies for the Finnish Stone Age lifeways, but owing to the turn of political situation this trip became essentially one of survival. He subsisted for the next years, as a fur hunter and trader, and visited both Japan and Alaska during his stay in eastern Siberia (Fig. 3). In 1919, Pälsi finally made his way home to the

Pälsi, Sakari, Fig. 2 Mongolian shaman Ötšir-böö in the Bajan-gol Valley in 1909 (Photograph: Sakari Pälsi 1909, National Board of Antiquities VKK156:6, CC BY 4.0)

newly independent state of Finland, by boat via India, Suez Canal, and United Kingdom. Unfortunately, this long expedition resulted only in popular articles and travel monographs, and the scientific results were never published, like for most of his later career.

After the Siberian experience, Pälsi shifted from archaeology towards ethnology, participating, for example, in the work of the Ethnological Film Ltd. He had experimented with ethnological filming already on the Siberian expedition; these films were found posthumously in 1975, and digitally restored in 2015. Besides Finland and Russian Karelia, Pälsi also carried out ethnological work amongst the Finnish immigrants in Canada in 1927.

Pälsi took part as a war correspondent on the Finnish military expedition of 1921–1922 to Soviet Union, and again during the Second World War in 1940–1942, despite being already 60 years old at that time. He also conducted his last excavations during the war in 1944, under Soviet artillery fire; this became the last excavation directed by Finnish archaeologists until the 2000s in the so-called Ceded Karelia (nowadays Russia), the birthplace of the Finnish Stone Age studies (Nordqvist 2017).

Pälsi was also one of the early members in the Social Democratic Association of the University Students (YSY), founded in 1905, and was a national activist during the "years of oppression" by the Tsarist Russia in the turn of 1900s. As an example, in 1906, he acted as a sleigh driver smuggling the famous Russian dissident Maksim Gorki out of Finland (then part of Russia). Pälsi advocated through his life an "idealistic socialism," which worldview also colored his academic research and interpretations (Seitsonen 2017).

Besides being a skillful and innovative archaeologist, who strongly developed the fieldwork methods and the use of anthropological analogies, Pälsi was also an adept photographer and cinematographer, an ethnologist, and a productive popular writer. He popularized both archaeology and ethnology, and wrote, for instance, the first popular synthesis of the Finnish Stone Age (Pälsi 1916), and the first Finnish archaeological fieldwork manual (Pälsi 1939). In his later life, Pälsi became publicly renowned for his popular travel writing and photography. On top of this, he authored several children's books and wrote also the first Finnish palaeo-fiction novel, founded on his decades-long archaeological and ethnological expertise (Pälsi 1950).

Panamá Viejo (Old Panama) Archaeological Site

Beatriz E. Rovira
Universidad de Panamá, Panamá City, Panamá

Historical Context of Panamá Viejo Site

A few years after Vasco Núñez de Balboa arrived in the South Sea (1513), and around a quarter of a century from the Spanish conquest of America, the city of Panama was settled in 1519. This was preceded, in what was called Tierra Firme, by a few settlements in the Atlantic watershed. It must be highlighted that, among them, Santa María la Antigua del Darién was the first city to be formally entitled in 1510. Indeed, the city of Panama results from Pedrarias Dávila's transfer of that settlement to the Pacific coast to a coastal village governed by Chief Cori.

From 1516, the Spanish presence on the Pacific watershed was overwhelming, although it was not until 1522 that the foundation of the city of Natá de los Caballeros was formalized (in the present-day province of Coclé, Panama Republic). In the second decade of the sixteenth century, the Spanish arrived in Peru as explorers, and from 1534, when an expedition of conquest captured the Inca emperor, Panama City acquires an important role in the colonial economic system becoming the first European port in the Pacific slope of the American continent, connecting the precious metal deposits of the Andean zone with the metropolis (Mena García 1992). The establishment of the crossing axis from Panama to Nombre de Dios (the latter was replaced by Portobelo by the end of the sixteenth century) constituted a very powerful driving force for social and economic transformation: fundamental protagonist of the Atlantic commercial circuit constitution and a starting point, for better or for worse, of the current world system.

The destruction of this city, and therefore the need for its relocation, came in 1671, when the English corsair Sir Henry Morgan attacked and sacked it. This relocation was included in the plans of the groups of power due to the evident vulnerability of the location. Register of such concern is found in Bautista Antonelli's plan (1586) which, in addition to presenting significant information about the urban layout, shows a proposal for a fortification that never came to fruition (Fig. 1).

The relocation of the site known at present as Casco Antiguo de Panama or San Felipe takes place in 1673. From then on, old Panama in ruins became a quarry for the new city and began to be invaded by the jungle. Jesuit Bernardo Recio's testimony (mid-eighteenth century) is eloquent:

> I was able to come to know what it was like since I have had the opportunity to visit that site many times because, as in the last years, I was in charge of the school of Panama, in whose new church I was engaged, *I used to go there for the same purpose other many neighbours went, that is, to remove materials from its ruins for the new Construction, buildings or structures*. I confess that these walks were for me great recreation and I relieved my spirit with pleasure walking through a plain and peaceful way, and finding myself in that solitude, I was moved to many affections: terror, admiration and mostly pity to see such a magnificent city destroyed, as it was shown by such beautiful stones and columns that we took out and by some buildings still so tall and half kept together, since, apart from the main church, which showed greatness and the houses of the city, which boasted magnificence; some paintings, which still adorned its walls were seen here in the church of Santo Domingo; a beautiful arch and in some parts great traces and relics of the old greatness were seen in the church of the Conception nuns. . . . (Taken from Mena García 2007)

A Great Demographic Transformation

Although the demographic information for pre-Hispanic times in America is based on more or less credible estimates, there is no doubt that

Panamá Viejo (Old Panama) Archaeological Site, Fig. 1 Plano de la ciudad de Panamá, de Bautista Antonelli (1586). (Biblioteca del Museo Naval, Ministerio de Defensa, Madrid, España)

the indigenous population declined dramatically throughout the region as a consequence of the Spanish conquest of the Panama Isthmus. From paleoecology, the analysis of sediment columns obtained both in the east and in the center of the country provides information about the history of human alteration of local vegetation, indicating the recovery of the forests from the sixteenth century, a reflection of a depopulation process (Cooke and Sánchez 2004).

Indirect evidence of the demographic collapse is the regular expeditions carried out as far away as Nicaragua, with the objective of capturing natives to be employed in forced labor, until this practice was explicitly prohibited by the crown in 1532. There is no doubt that in different parts of the isthmus, some indigenous populations survived, in refuge areas, far from the centers of labor exploitation. The descendants of these populations are the members of seven native linguistic groups that currently inhabit the Panamanian territory.

The data on the city's population, although scarce, are illustrative. In 1533, approximately 500 Indians resided in the urban area or its surroundings; this number declined to 120 in 1544 and to 100 in 1547. By 1603, only 70 indigenous people remained in the "district of Panama," living in very precarious conditions in San Cristóbal de Chepo, about 30 km to the east, and on the islands of the Panamá Bay (Taboga and Isla del Rey). In the "Description of Panama" of 1607, it is mentioned that 24 indigenous people lived in the city of Panama (13 men and 11 women) (Mena García 1984: 82).

The drastic reduction of the autochthonous population that too early deprived the colonial enterprise of its labor force was soon remedied as the slave trade provided a profitable business by importing large numbers of African slaves. The

first of a long list of "importations" occurred in 1532. As an illustration of the ethnic composition of Panama City, Alonso Criado de Castilla offers in 1575 detailed information on the slave population: there were about 800 Europeans and 1,600 Africans employed in domestic tasks and other urban services. This author also mentions the existence of more than 3,000 slaves working in the trans-isthmian traffic, cattle rising, agricultural activities, and pearl fishery in the jurisdiction of the Panama Audiencia (Ward 1993).

Castillero (2006), based on diverse sources, suggests that the city had hardly surpassed 7,500 inhabitants. Of these, the "neighbors," that is, the elite of Spanish origin, would reach the number of 500 or 600 between 1620 and 1630, and then it was reduced to around 300, a figure that would remain until its relocation.

The Site of Old Panama in the Construction of the National Imaginary

In Romantic Europe, travel books were one of the most fertile literary genres. The qualifier "picturesque" was incorporated into the titles of many publications that, from 1830 and during the following four decades, were widely spread. Most of the authors of these works, mostly, were eccentric aristocrats who enjoyed economic surpluses to undertake these escapes from "civilization" and face the exotic "nature" that embodied both "savagery" and "paradise."

The travellers who left testimony of nineteenth-century Panama were fundamentally North American, and their arrival on the isthmus did not obey the romantic impulse to know other horizons; the reasons were much more prosaic, linked to the interventionist policy of the United States in New Granada, legitimized by the Mallarino-Bidlack Treaty. Their views of the Panamanian society were mixed, as was the case of their European contemporaries around other horizons, by the vision of progress as the imposition of humanity on nature. The approximation to local landscapes and customs was saturated with exoticism. The arrival in Panama produced in them the sensation of crossing borders, the confrontation between the "American" way of life and that of the tropics (with its ingredients of sensuality, laziness, and disorder). It is not uncommon, however, that they succumbed to "barbarism," which in occasions seemed full of charms.

Among the travellers who visited the ruins of Panama la Vieja, Robert Tomes was one of the numerous travellers invited by the Railway Company to the inaugural journey from "ocean to ocean," in 1855. The past of the city *founded by Balboa* (sic), now covered in vegetation, with large trees and vines, was almost dreamlike for him: "the houses (. . .. . .) where built of cedar, very curious and magnificent, and richly adorned, especially with hangings and paintings, much gold and silver" (Tomes 1855: 208). New York publisher Harper's Brothers published several of Tomes' journalistic works in the mid-nineteenth century, surely a good reader, quotes long paragraphs from the "bestseller of piracy": *History of the Buccaneers of America de Exquemelin* (English version of 1741), abounding in details of the attack on Panama and the consequent looting. The city in ruins appears then as real scenery of pirate and corsair incursions: perhaps the prevailing narratives of the global world perspective of the nineteenth century. Let us remember, for example, that Emilio Salgari (1862–1911), an epigonic romantic and one of the most widely read adventure writers of the pre-television era, a permanent seeker of imaginary horizons, wide in time and space, could not prevent succumbing to old Panama landscape (which perhaps did not know personally) using it as the setting for some of the episodes of *Yolanda, The Daughter of the Black Corsair*, in love, for more details, of tender and protective Henry Morgan (Salgari 1977).

It is in the reading of Oran's *Tropical Journeyings* published in Harper's New Monthly Magazine in 1859, illustrated with superb drawings that show the site of Panama Viejo as a ruined city, partially invaded by the tropical forest, where we find, besides the romantic narrative, a vision from the bottom (Oran (Pseudonym) 1859). Indeed, Oran recounts a visit to the site of the ruins, where he and his companions were guided by Marco Segundo, who was inhabitant of one of

the three existing huts in the vicinity of the old Cathedral. This person, native of a nearby town of around 70 years of age, sought refuge, according to his own words "from bad companies." Contrary to the romantic spirit, the temporary escape from "civilization," in search of the exotic, there is here a decision of estrangement, of escaping from marginality, from misery, perhaps from the law. He obtained money by selling the vegetable fiber ropes he made, which he sold sporadically in Panama City, although his economy was basically subsistence. From Oran's story, we could point at Marco Segundo as the most remote predecessor of the tourist guides of Panama la Vieja, thinking that the habit of outing to places near the city seems to have been institutionalized after the second half of the nineteenth century, due to the influence of the American presence on the isthmus. At that time, historical, cultural, and ethnic tourism began to develop in Europe (along with health tourism) but was not shaped with a clearly mercantilist orientation until well entered the twentieth century. From then on, tourism crystallized some of its characteristic features, which, with few exceptions, are still typical of this activity: spectacularity, superficiality, decontextualization, and emphasis on exoticism associated with an ethnocentric vision of the others.

When the national state was constituted, in the year 1903, Panama Viejo begins to arouse interest as an emblem of the newly inaugurated country. The vestiges of the colony served the purpose of demonstrating the existence of a defined identity from a long time ago, and that it was not merely a creation of the United States. The first historical investigations are carried out, some of them promoted by the atmosphere that surrounded the celebrations of the fourth centenary of its foundation in 1919.

The site or some of its elements have been incorporated from the constitution of the Panamanian state to a large repertoire of communicative and expressive actions (in multiple supports): coat of the national police, money paper, stamps, painting of buses, letters of *boleros*, poetry, and diverse crafts (including *molas*). Even in the ephemeral urban graffiti "paintings," the emblematic element has been and is the tower of the Cathedral, massive and of medieval airs. Seen from the sea, it suggests that defensive functions as the watchtower were added to the fact that it was an important reference in navigation. Some travellers' comments seem to reinforce this idea. At the beginning of the nineteenth century, Baleato (Cuervo 1892) says the following about the hydrology of the "inlet" (sic) of Panama and the recommended routes to enter Perico anchorage:

> . . . The entrance to Perico anchorage, with favourable wind, is checked, if one wants to, up to 2 cables to the East of the Farallón and continuing at the same distance on its part to the North. To give anchorage as planned (13): but when it is taken onto the bottom, which usually happens at the North's breeze station, the bottom-down of the outside or Meros will be protected, and the padlock or Panama La Vieja, whose markings are as follows:
> [. . . . . .]
> Bajo del Candado or Panama, La Vieja
> Tower of Panama la Vieja N. 3° O.
> Punta de Paitilla N. 75° O.
> Medianía of the towers of the Panama Cathedral S. 78° O.
> Islita Flamenco S. 30° O.

Suggestively, in 1863, two North American captains say that "the tower is still, in the afternoon, a remarkable object from the anchorage" (Parker King and Fitzroy 1949, cited by Guzmán Navarro 2001: 35).

From the constitution of the Panamanian state to the fiftieth anniversary of the nation-state (1903–1953), many more efforts were devoted to the conservation of the Hispanic heritage than to the pre-Hispanic one. The colonial and post-colonial referents were symbolically more powerful in the construction of the national identity (the first rules for the preservation of the "historical monuments" date back to these years). By then, and consistent with world currents, the conservation of architectural monuments occupied a central place during the first half of the twentieth century, a situation that then begins to change slowly, when the delineation of goods considered in the category of heritage begins to expand.

"History" and "archaeology" were two separate worlds. The patrimonial rhetoric, as a reinforcement of patriotism, only included the first. The archaeological remains were associated

with the pre-Hispanic, while the vestiges of the colony constituted distinctly "historical" events. Therefore, Panama Viejo was not perceived as an archaeological site, but as a historical site. This panorama is modified from the second half of the twentieth century, moment that corresponds, in the international arena, to the configuration of the so-called new archaeology.

On the other hand, Panama Archaeological Society, created in 1949, is constituted and operates intensely, in great part of the territory, but basically in the canal strip. It is an association of archaeology amateurs formed by residents of the Canal Zone, who without due training or professional advice devoted themselves for two decades to the search and non-systematic excavation of archaeological sites (1984: 17).

In spite of this, the activities of this association highlighted the pre-Hispanic occupation of Panama Viejo site, through Leo Biese's work (1964), and also gave rise to the knowledge of the sixteenth and seventeenth centuries ceramic complex, which a number of investigators such as Rouse, Goggin, Long, and Cruxent would begin to be in charge from then onward and would mark the entrance of Panama to the field of historical archaeology. The inclusion of Panamanian majolicas in Goggin's emblematic book (1968) could be considered as a foundational milestone in Panamanian historical archaeology.

In the 1970s and 1980s, there began to be official concern on the part of the Panamanian Tourism Institute and the National Institute of Culture, to promote the touristic use of the site; in order to do so, the carrying out of several plans of action is hired, but they are not enhanced.

From 1989 (post-invasion), a new trend in the management of cultural resources begins to be defined, which, although legally under the ultimate responsibility of the state, proposes that they be administered through non-governmental or mixed associations such as foundations or patronages.

Within the framework of this trend, the Panamá Viejo Patronato (Board) is created in 1995, an institution of mixed private-state and nonprofit regime that administers the 28 protected hectares that make up the monumental complex. Its basic objectives are focused on the conservation, protection, promotion, development, and enhancement of the site. In 2003, the Patronato's dedicated work made it possible for Panama Viejo to obtain the declaration of UNESCO World Heritage Archaeological Site.

Panama Viejo Archaeological Project: Scope and Achievements

In accordance with the normative framework of the agreed master plan of interventions, the setting up a comprehensive program of archaeological investigations is created, with the aim of regulating the excavations and the registration method. In 1996, the first steps were taken to structure a permanent program of archaeological interventions (Martín and de Arango 2013). In this way the Archaeological Project of Panama Viejo began, consolidated by Beatriz Rovira (2000) and currently coordinated by Mirta Linero Baroni (2014), which to the present has become a model for the archaeology of the country and the region. This is even more significant due to the lack of institutional spaces and cultural policies in the Panama Republic that effectively promote this type of research aimed at the preservation of historical heritage, and which are not usually considered priorities in the instances of planning and decision-making at a national level.

From the beginning, the Panamá Viejo Patronato's archaeological program has developed research lines from rescue projects or articulated with architectural interventions. The recovery of the urban layout (blurred by the different natural and anthropic variables responsible for the formation of this site) and its interpretation were based in part on the results of excavations.

Besides, the understanding of built spaces (religious, administrative, and domestic), about which written information is scarce, made it possible to register archaeological contexts of different ages. The analysis of the information thus collected generated multiple lines of research, which account for several master's and doctoral theses written by local students and various international academic institutions, as well as multiplicity of articles published in specialized

journals. Since 2006, the Board of Panamá Viejo has its own annual scientific journal, *Canto Rodado*, which serves to the purpose of spreading heritage issues in the academic sphere.

Although the site has been patrimonialized for its values related to the Hispanic heritage, the history of its human occupation dates back to pre-Hispanic times. One of the merits of the archaeological project has been precisely to substantially expand the range of these values. Upon the arrival of the conquistadores, the isthmian territory was structured in flexible political entities of the chieftainship type, with dense populations in the estuaries of the rivers. Panamanian pre-Hispanic archaeology is one of the most advanced in the region; however, there is not enough information available about the eastern part of the country. Incursions in the levels of pre-Hispanic occupation of Panama Viejo contributed significantly to supply this deficiency.

As for the colonial archaeological component, even though the availability of written documents has sometimes led to underestimate the importance of the material remains to know that period, research has revealed unknown aspects of everyday life in the city, especially from the documentation of the rich ceramic collection obtained.

It is interesting to mention, perhaps because it is a general problem in the practice of archaeology in monumental sites, that the overwhelming presence of construction remains initially generated, in the decision instances, the vision of archaeological work as merely technical, oriented to the recovery of buried architectural features and subordinated to the work of architectural intervention. Little by little and largely due to the incorporation of professionals trained in interdisciplinary perspectives, such narrow conception evolved toward integrating positions.

The contributions of archaeology were, in addition, important factors for that perception to be transformed and placed as a central element of the site's patrimonial activation, especially in the museographic and spreading strategies. Regarding the investigation, some of the most significant contributions are summarized below:

Archaeology of the Site's Architecture

The information provided by the two historical maps available, one from 1580 (by Bautista Antonelli) and the other from 1609 (by Roda; Fig. 2), and a drawing from the Casas Reales

Panamá Viejo (Old Panama) Archaeological Site, Fig. 2 Plano e la ciudad de Panamá, de Cristóbal de Roda (1609). (Archivo General de Indias, Sevilla, España)

(Royal houses) of 1590 (Archivo de Indias, Sevilla, MP Panamá 236) was an important starting point. The data obtained from the observations of the existing structures and archaeological excavations were added to it. The site had been intervened in the 1950s of the twentieth century on the occasion of the celebration of the fiftieth anniversary of the republic. Of these works, the existing documentation is almost none; so one of the archaeological challenges was to discern between original pavements and those laid during these works. Not always the presence of artifacts allowed an approximation to the age of the traits. However, as the work progressed, it was possible to establish a constructive typology that made it possible to discriminate between the two, revealing an intention to make the distinction possible in the future. This episode is interesting, especially because of the fragility of the historical memory in the country so strongly impacted by the crossing function and by a deep-rooted short-termism.

Several sesaons of electrical resistivity prospection contributed to guide the archaeological work carried out to solve some questions about the streets' layout and in relation with some of the buildings' floors. The importance of interdisciplinary perspectives, the results of research aimed at interpreting the urban layout, the spatial organization of the ruins of San Francisco convent (Löbbecke and Tejeira 2007), the Nuns of the Conception Convent (Fig. 3), Santo Domingo Convent (Fig. 5) (Linero Baroni and Muñiz Álvarez 2016), of the Cathedral (Fig. 4) and of the so-called Casa de los Genoveses (Gaitán Ammann 2012) are interesting examples. Archaeologically speaking, documenting the floor and other construction features of wooden houses was enhanced. The collection of metallic construction materials constitutes a valuable source that has contributed to the knowledge of early architectural techniques (Meza and Linero 2016: 65–84).

Indigenous Population of Panama Viejo

The first inhabitants of the isthmus, more than 10,000 years ago, have left tangible footprints in different parts of the country, especially in the Chagres River basin, where projectile points used for hunting were found. More than 5000 years ago, the populations had started cultivation practices of a variety of plants. This activity, complemented with hunting and fluvial and maritime fishing of a multiplicity of species, made it possible to sustain societies that over time were incorporating new techniques and modifying their patterns of social organization. The great biodiversity favored exchanges and constituted the fundamental pillar of the economy.

A few centuries before the Christian era, the Panamanian population was grouped into village settlements with houses adapted to the tropical environment, and they produced objects that arouse admiration for their technique and aesthetics (such as the case of polychrome or modelled pottery and goldsmithing). Upon the arrival of the conquerors, a time when written documentation began to be available, the larger populations were located in estuaries and lower courses and some of the main rivers, structuring the space in relatively flexible chieftdom territories.

In general terms, the pre-Hispanic archaeology of the Republic of Panama is one of the most developed in the Central American area. However, the eastern part of the country, for multiple reasons (it is a sparsely populated area, somewhat marginal in the country's economy), has been relegated to the background. The archaeological program of Panama Viejo constitutes an opportunity to overcome this shortfall. In effect, the colonial foundation was carried out in a territory occupied by indigenous inhabitants, although a short time later, as mentioned before, this population practically disappears from the city.

As it was pointed out, the first news about pre-Hispanic finds on the site dates back from the 1960s (Fig. 6), when a series of earth movements to level the surface of a modern cemetery situated in an area adjacent to the protected area exposed a dense concentration of material remains.

Panamá Viejo (Old Panama) Archaeological Site, Fig. 6 Vasija prehispánica. Museo Antropológico Reina Torres de Araúz, Panamá

A series of excavations carried out within the framework of the Panama Viejo archaeological project has enabled to propose an absolute chronology for the pre-Hispanic component of the site, which is concentrated between 859 and 1250 AD, with a range that goes from the year 500 until the time of the Spanish conquest. The promotion of the pre-Hispanic archaeology of Panama Viejo site has special importance for ancient Panamanian history. The possibility of locating pre-Hispanic deposits (unthinkable in the rest of the densely occupied metropolitan area) enables the projection of a regional perspective. In fact, due to the tourist enterprises of the Las Perlas archipelago, archaeological investigations have been carried out that indicate around 5000 years back as the oldest date of these islands' occupation. For this reason, the connections between the mainland along the Pacific coasts of Eastern Panama and with northwestern Colombia, an area known as Gran Darién, are emerging as an important research topic in the immediate future.

A discussion of the ceramic and lithic materials found in several excavation campaigns carried out since 1996 and their regional correlations with both the Gran Darién (Panamanian east and northwestern Colombia) and with the central region of the country can be found in Martín (2006–2007) and Pearson (2006). The pottery is predominantly unslipped or red paint; in some cases the vessels feature anthropomorphic and zoomorphic modelled ornaments. There are frequent pieces

similar to those corresponding to the styles called Cubitá and Conte Temprano of the central region of the country, as well as ceramics located chronologically at the time of the conquest. It is possible that these are local versions that emerged as a result of the intense contacts and exchanges that existed between the coastal communities of the Panama Bay, which included, as we said, Las Perlas archipelago populations (Cooke and Sánchez 2004; Martín and Sánchez 2007).

The sample of pre-Hispanic lithic materials (about 500 specimens) was studied typologically and technologically. There is an industry of flakes, another of blade points, and a third of polished stone. The general characteristics of this set include unifacial flaking, opportunistic flake industry, production of thick flakes, points on blades well elaborated from cores with opposite platforms, and possible existence of carving specialists. While most of these features are typical of the Panamanian lithic industry of the ceramic period in general, it is observed that a very skilled manufacture of points on blades is a distinctive element in the whole of Panama Viejo (Pearson 2006).

Of the scarce information about houses' remains recovered in the field of pre-Hispanic archaeology of the country, it corresponds to Panama Viejo the evidence of two circular structures, one defined by post holes and the other by pebbles, and for these contexts, calibrated radiocarbon dates (880–1020 AD and 990–1260 AD) are available (Martín 2006).

Daily Life Things of the Colony

The collection of colonial artifacts is very broad, and an intense work is carried out in its conservation, cataloguing, and documentation. On the one hand, they nourish the museum exhibitions, and on the other hand, they constitute the platform for the development of specific research lines.

The study of colonial ceramics has been perhaps the most dynamic up to the present; it has been possible to characterize the assemblages corresponding to two moments in the history of the city: broadly speaking, the end of the sixteenth century and the seventeenth century. Unfortunately, no earlier contexts have been found, although we know their composition partially from very preliminary investigations carried out in older colonial settlements in the Isthmus of Panama (mainly Nombre de Dios).

For example, until the end of the sixteenth century, ceramic sets for domestic use have very high percentages of European majolica (around 80%), despite the high costs of trans-isthmus freights, and, of course, the fragility of this merchandise would complicate its transportation. Tastes and preferences undoubtedly qualified the cost-benefit equation. The tin-glazed ceramic collection includes pieces with blue-on-blue decoration, a Genoese (Ligurian) style, polychrome with Italian reminiscences, and austere pieces of Moorish tradition. It also highlights the very early presence of Chinese porcelain. The habits of consumption of goods manufactured in the city have a global air; on the contrary, at the start of the seventeenth century, the largest proportion of ceramic artifacts seems to be locally produced, while, for example, 20% of tableware is still imported. Outstanding in this period is the so-called Panamanian majolica (Fig. 8, 9 and 10), mentioned in literature since the 1960s. Originally considered Peruvian production (Goggin 1968), it was associated with Panamanian workshops accidentally found and destroyed in 1958. Unfortunately there are no photographs, no drawings, and no report describing this finding, so their status as data was waiting for decades for the possibility of confirmation. For those dates, however, the finding of trivets, nails, and refractory boxes or blankets was recorded and published, considered as conclusive proof of the existence of local majolica production. Other indirect evidence of the presence of workshops that strengthened the idea of a local manufacturing is that such ovens were reported near the course of the Rio Abajo River, north of the site, a propitious location for pottery for its access to water, and also because it is an area close to Santa Ana chapel. This location was revealing if we take into account that, at least in Seville, the members of the potters' guild had their brotherhood in a chapel of the Santa Ana Church in the suburb of

Triana. Very recently, during rescue archaeology work carried out in the sector, Tomás Mendizábal (personal communication, 2016) identified the structure of two ovens, which would close the chapter on doubts about the origin of Panamanian majolica. The following types are usually distinguished, which present particular frequencies according to the chronology of the deposits: Panama Plain, Panama Blue on White (Fig. 8), and Panama Polychrome (Fig. 7 and 9).

From the Panama Viejo archaeological project, contributions were made about its chemical characterization through the use of neutron activation (Rovira et al. 2006), its distribution (Rovira 2001), and around its aesthetic patterns (Rovira and Mojica 2007).

There are still many questions about this production, mainly the lack of documentary support written about the Panamanian majolica production. This surprises greatly, since the operation of workshops would require (this is also suggested by the homogeneity of the sample) the existence of a guild with its standards, such as those of Puebla, referred to by Lister and Lister (1984). We can undoubtedly say that up to now, Panama potters guild is invisible in the documentary archives. It should be taken into account here that the absence of references in this regard could be due to the low social prestige that potters probably enjoyed in medieval and post-medieval times and, the very general allusions about pottery, that in most the cases prevent relating an artifact or a particular group of them to the written testimonies. It can also obey the social value that Panamanian production had, in the context of the Spanish colonial world, as it will be discussed later.

Several findings in American sites have revealed a wide geographic dispersion of Panamanian majolica, mainly in localities along the South American Pacific coast, although its presence in the state of Chiapas has also been reported. The area of fundamental dispersion however as initially visualized by

Panamá Viejo (Old Panama) Archaeological Site, Fig. 7 Mayólica panameña policromada, siglo XVII. (Colección de referencia del Patronato Panamá Viejo, sub colección cerámica)

Panamá Viejo (Old Panama) Archaeological Site, Fig. 8 Mayólica panameña decorada en azul sobre blanco, Siglo XVII. (Colección de referencia del Patronato Panamá Viejo, sub colección cerámica)

Panamá Viejo (Old Panama) Archaeological Site, Fig. 9 Mayólica panameña policromada, Siglo XVII. (Colección de referencia del Patronato Panamá Viejo, sub colección cerámica)

Lister and Lister (1976) has been that of the viceroyalty of Peru. According to the extent that the study materials of the colonial period in different parts of South America become important, new records will undoubtedly be added. Such is the case of some Panama Polychrome sherds found in Cayastá (Santa Fe la Vieja, Argentina) and in Buenos Aires. Some Panamanian majolica sherds have also been recognized in Popayán (Colombia) in surface recollections made on monuments affected by an earthquake.

INAA analyses of pastes have shown a great homogeneity in the composition of the sample of Panama Viejo and some sherds classified as Panamanian majolica found in Cuenca (Ecuador). It is interesting to mention that a group of ceramics called Redware also presents a chemical composition similar to that of Panamanian majolica. From these data the idea of the existence of a diversified pottery production in Panama begins to take shape.

As for the chromatic spectrum used in the painted decoration of the Panamanian majolica, we can say that it was small, unlike the production of other centers in which the Italian influence with its profuse polychrome is evident (Talavera, Seville, Mexico, among others). As in the European medieval ceramics and in that inscribed to a Mudejar tradition (which was still prevailing in Valencia and Aragon), the use of green, magenta, and blue stands out. There are no zoomorphic or anthropomorphic motifs, heraldic, allegorical, or religious shields, only in truly exceptional cases.

One group of ceramics of global dispersion found on the site is very fine, red, and burnished which has been associated with vessels called in the specialized literature as the Guadalajara *búcaros* or *barros* of the Indies, bucarine mud, of great interest because of the abundance of data concerned with its social meanings: its connection with the bucarophagia, its articulation to the world of baroque collecting, its profuse mention in Spanish literature of the Golden Age, and its representation both in European painting of the seventeenth century and in the famous caste paintings of the following century (Fig. 10). Panama is a scenario with the potential to continue studying these materials, of which there were several manufacturing foci both in Europe and in America: the available historical documentation mentions the manufacturing center of Natá, in the central region of the country, as one of the production centers (Rovira and Gaitán 2010).

Innumerable objects that made up the cultural landscape of the site, among which are accessories of clothing and personal adornments; objects of various functions, such as rituals (medals and amulets); and those related with commercial activities (coins, lead seals, weights, among many others), are part of the collection of colonial artifacts.

Studies of Biological Remains

The analysis of animal and botanical remains has played an important role in the generation of knowledge about cultural practices (feeding, obtaining food, rituals, and funerary objects,

Panamá Viejo (Old Panama) Archaeological Site, Fig. 10 Pieza de cerámica roja fina, correspondiente a los denominados "búcaros de Indias", siglo XVII. (Colección de referencia del Patronato Panamá Viejo, sub colección cerámica)

among others) as well as about paleopathological and paleoecological aspects.

Some interesting considerations are derived from the identification of the domestic fauna, such as the large size of beef cattle, contrary to what common sense could indicate based on the characteristics of climate and soils, and of the non-domestic fauna analysis of a sealed context dated between 1580 and 1617, which made it possible to infer fishery practices and observe the considerable exploitation of terrestrial native species in spite of the development of livestock as evidenced by the abundance of deer, *saínos* (peccaries, *Tayassu tajacu*), and iguanas.

The comparison between samples of molluscs (bivalves and gastropods) of pre-Hispanic and colonial age clearly illustrates the changes in the diversity of species used. While before the Spanish occupation different ecological niches were exploited, the catches in the colonial era were limited to practically a few species of the intertidal zone (Martín and Rodríguez 2006).

In a recent paper, Aceituno and Martín (2017) present the results of the analysis of a type of botanical evidence little used, the analysis of starch grains. The material was extracted from lithic instruments from the colonial era, and the result was the identification of starch from cassava, corn, and beans, which illustrates the rapid adoption of local plants in the city inhabitants' diet.

As far as bioanthropology is concerned, the potential of interpretative possibilities offered by the excavation of funerary contexts is very broad. From contributions to the knowledge of conceptions about death as a biocultural phenomenon in general, paleopathological considerations and contributions to the history of medical practices, as well as studies on genetic variability that make it possible to venture not only to population origins but also to the way that conceptions about the racial, were socially and culturally constructed. The samples obtained in several archaeological contexts of Panama Viejo gave rise to this potential in part. Such is the case of those recovered at the San Juan de Dios Hospital (Scholkmann et al. 2006; Martin et al. 2009; Rojas-Sepúlveda et al. 2011 among others). A wide collection of burials excavated in the nave and atrium of the Cathedral are objects of Iosvany Hernández's PhD research, within the framework of the project "An Artery of Empire. Conquest, Commerce, Crisis, Culture and the Panamanian Junction (1513–1671)," of the Pablo de Olavide University (UPO), financed by the European Research Council within the framework of Horizon 2020 (ERC CoG 648535), directed and coordinated by Bethany Aram. This is a program that takes over an interdisciplinary perspective, integrating the analysis of archaeological, historical, and archaeometric data.

Projection

Since its inception, the Panama Viejo archaeological project has incorporated into its activities a wide range of initiatives that contribute not only to the generation of knowledge but also to its socialization, committing to dissemination work through diverse channels and training of human resources. Museum proposals, publications, and academic efforts occupied an important place in planning (Rovira and Martín 2008; Martín and Rovira 2012).

From the point of view of training, the modality of conducting short seminars on specific topics in which particular aspects of the interventions on the site, from an interdisciplinary perspective, has been motivating. Such is the case of the seminar that took place in 2015, about the experiences in the

cloister of Santo Domingo Convent, whose objective was to discuss the possibilities and achievements of the geophysical prospecting techniques, specifically the electrical resistivity tomography, the results of archaeological research, the contributions of the landscape perspective, as well as the interpretative relevance for the study of the historical evolution of the ruins and the use of new three-dimensional modelling tools.

In addition, the archaeological project develops an intense work, in association with different universities and research institutions. It is worth mentioning the realization of archaeological field schools, with the participation of students and young professionals, national and foreign, interested in specializing in the area of historical archaeology. The schools include archaeological excavations, complemented by workshops and conferences of researchers affiliated to different universities and research centers. Out of these experiences, five undergraduate, one master's, and four doctoral theses have been developed in the framework of academic programs of different universities in the country and abroad (University of Panama, University of Huelva, University College of London, University from Tübingen, Columbia University, and University of the Andes of Colombia, among others).

In 2005, the archaeology team of the Patronato Board of Trustees proposed the publication of a magazine in which the complex field of heritage from its multiple perspectives would be discussed, which would make room for the scientific production of the institution but which also included international contributions. In this way, *Canto Rodado* starts its publication, uninterrupted until now, with an annual frequency, but with the challenge of increasing its frequency in the future and consolidating itself as an inter- and multidisciplinary dissemination organ.

Panhellenism

Michael Scott
University of Warwick, Coventry, UK

Introduction

The *Oxford English Dictionary* defines panhellenism as patriotism based on the concept of Greece as a whole. This broad understanding of the term has been much in vogue since its invocation in the nineteenth century by early historians of Greece, like G. Grote and John Fiske, who sought to emphasize the reality of an ancient, panhellenic, "united" Greece in response to current political events, particularly the struggle for Greek independence and a "return" to a united, panhellenic, Greece (cf. Mitchell 2007: xv–xxii).

Matching the modern term panhellenism (let alone its meaning) to the ancient Greek world has, however, proved more difficult: there is no example of the use of *panhellenismos* or other term specifically for the phenomena of panhellenism in the ancient sources. Scholarship has concentrated instead on finding references to terms that allude to such a concept.

The most obvious is in the Roman world, with the advent of Hadrian's *Panhellenion* (Hadrian's union of Greek poleis within the Roman province of Achaia) in the second century CE. The

Panhellenion sought to place emphasis on kinship and cultural Greek ties and sparked a wider use of the term, for example, the panhellenic games in Athens. Yet even this *Panhellenion* was not panhellenic in the sense that it included all parts of a united Greek world but was rather focused on the metropoleis of old Greece and their overseas colonies (cf. Spawforth and Walker 1985: 81–2).

In the archaic and classical Greek world, scholars have pointed to the (rare) use of "panhellenes" and to calls for (different kinds of) Greek unity in different ancient authors (discussed below). Scholars have also occasionally used the concept of panhellenism to argue for the wider existence of particular genres of artistic creation, such as tragedy (e.g., Taplin 1999), and the similarity of "Greek" material culture across its different poleis, thus by extension minimalizing the "uniqueness" of Athenian art (e.g., Morris 1998). The most important application of panhellenic to archaeological material and sites, however, has been as a description for a group of important Greek sanctuaries: Olympia, Delphi, Isthmia, and Nemea (those which hosted the "crown games" and were part of the "periodos" circuit). As a result of this label, it has often been assumed that the function and effect of these sanctuaries was to host and foster "panhellenic unity" through the different activities on offer at each site.

Recent scholarship, however, has continued to re-investigate the appropriateness of the term panhellenism and its meaning as "a union of all Greeks" to the ancient reality (and even ideal) in both literature and material culture. As a result, its current definition in the *Oxford Classical Dictionary* evokes a subtle move away from the earlier blanket concept of unity towards a comparative idea focused around similarity and difference. Panhellenism is "the idea that what the Greeks have in common as Greeks, and what distinguishes them from barbarians, is more important than what divides them" (Hornblower and Spawforth 2003: 1106).

Definition

Use of the ancient Greek term "panhellenes" is rare before the Roman period. Early examples are Hom *Il*. 2.530; Ar. *Peace* 292, 302; Pind. *Isthm*. 2.38, 4.29; and *Pae*. 6.60 (fr.52f = D6Ruth). Nor do all these examples necessarily mean "all the Greeks." Hall in fact argues that the term "hellenes" actually began as "panhellenes" (cf. *Iliad* 2.530), meaning not "all of the Greeks," but the "the most Greek of the Greeks" (Hall 2007: 272–4). Much more frequent, of course, are what have been termed "appeals" to concepts of panhellenism, all with reference to different types of community. The most famous is that of Herodotus (8.144.2), in which Greek kinship is based on common language, blood, sanctuaries, sacrifices, and common ways of life; but other such definitions of community can be found in, for example, Hdt. 7.132; 8.121; 9.81 and in inscriptions like Meiggs and Lewis (1988) no. 24 (line 4). Scholarship has occasionally emphasized the very explicit political opportunism of such appeals, particularly by Athens (e.g., Perlman 1976). Yet as a result of widening the net for panhellenism, many scholars have felt the necessity to add descriptive adjectives to narrow down the vagueness of panhellenism, such as "functional" and "true" panhellenism (Neer 2007: 226) and "strong" and "weak" panhellenism (Mitchell 2007: xviii). Such a widening net has also meant increasing overlap with scholarship on differing concepts of "hellenism," to the extent that the necessity and value of the term panhellenism as distinct from hellenism have been questioned ('what is so "pan" about "panhellenism"?).

In its application to sanctuaries, and particularly Olympia, Delphi, Isthmia, and Nemea, there has also been increasing scholarly uncertainty. This has focused firstly around the date at which each of these sanctuaries can be said to have acted as "panhellenic" entities. Snodgrass, for example, claimed that Delphi was acting out a panhellenic role from the eighth century BCE (Snodgrass 1986), yet Morgan has argued that no such role can be envisaged before the seventh century BCE (Morgan 1993). Scott has continued that line of enquiry, by questioning the role of Olympia and Delphi as always places for all Greeks into the classical period (Scott 2010). Secondly, scholars have criticized the distinction of these four sanctuaries as panhellenic and thus different from others: they were not, as has been claimed, in

receipt of unique services, the only sanctuaries that attracted large panhellenic crowds, nor the only ones which were open to all Greeks (cf. Scott 2010: 257). Thirdly, scholars have noted a wide range of differences in activities, ownership, and audience between the four panhellenic sanctuaries themselves (cf. Neer 2007: 226). Equally, other scholars have rejected the usefulness of the term panhellenic as a group description at all, with more recent surveys of these sanctuaries speaking of them as "interurban" rather than panhellenic.

Key Issues/Current Debates/Future Directions/Examples

While the use of panhellenism as a blanket term meaning "the unity of all the Greeks" to describe the reality of ancient Greece has faded, as well as its use as a distinguishing term for a collective grouping of particular sanctuaries, the scholars have rightly continued to consider moments, genres, places, and ways in which notions of (different kinds and levels of) Greek unity may have had value in the ancient world as ideal and/or reality. In terms of chronology, most scholars agree that the acme for sentiments of panhellenism during the archaic and classical periods was in the aftermath of the Persian wars (Mitchell 2007: xvi). These events also gave a particular flavor to the concept of Greek unity as something conceived in opposition to what it was not: Persian/barbarian (see the *OCD* definition above). This was reinforced in the late classical period, when several ancient authors refer to the post-Persian wars (and the anti-barbarian Greek unity that came with it) as a "golden era," which their worlds should seek to emulate (e.g., Gorgias, Isocrates, Demosthenes, cf. Low 2007), and when Philip based his Hellenic league loosely around the same aim (attacking Persia). In terms of place, though the description of the periodos sanctuaries as panhellenic has been deservedly recognized as problematic, no one denies that there were panhellenic (as well as equally un-panhellenic) aspects to their activities, audience, and reputation, both of which often existed simultaneously and which were constantly changing over time. This increasing recognition of the dynamic and multiplicitous perception and experience of sanctuaries continues to provoke new insights into the complex and crucial place of sacred spaces in ancient society and their frequently oscillating importance within the wider landscape (such as the recent examinations of the early panhellenic outlook of the sanctuary of Kalapodi as on par with that of Olympia and Delphi: Felsch 2007: 227). As such, concepts of panhellenism continue to find their place within the wider spectrum of hellenism, not as a static construct of unity but as an evolving part of the polyvalent discourse of Greek identity.

Paper: Preservation and Conservation

Hanna M. Szczepanowska
Smithsonian Institution, Museum Conservation Institute, Suitland, MD, USA

Introduction

Paper is one of the oldest man-made materials which origin is conventionally dated to 105 CE when paper was described for the first time by a Chinese script (Hunter 1978). From its invention, paper has been used for many applications, mainly as a material on which art was created and documents written. The container and packaging industry relies on paper. Clothing, umbrellas, and a variety of daily accessories made of paper point to a multitude of paper uses. Each application requires different optical, physical, and chemical properties to meet the users' expectations. Properties of paper, longevity and response to adverse conditions, rely on properties of fibers that compose paper, process which fibers undergo, and characteristics of additives. Understanding the materials and basic principles of paper manufacturing serves as basis for designing a long-term preservation and conservation strategies.

Although its use is ubiquitous, paper is prone to warping, tearing, and staining as a result of mishandling, exposure to light, or changes in temperature and humidity in the environment. Although not all these processes governing chemical and physical changes in paper are fully understood, recognizing that there is a relationship between the environment and paper alteration guides principles of preventive conservation. Conservators are capable to reverse only some of the deterioration processes aiming to stabilize paper and regain aesthetic enjoyment of art and artifacts made on paper.

Definition

Paper is a web of fibers, sizing, and fillers assembled with a great degree of heterogeneity in distribution, shape, and chemical composition. Paper is a three-dimensional structure of fibers and voids between them (Bristow 1986). Surface of paper has different properties than bulk. Smoothness or roughness of the paper surface is imparted by application of sizing (or its absence) and different methods of flattening, while paper pliability, rigidity, density, or weight are engineered during paper processing. Fiber composition, additives, and manufacture of paper have impact on longevity of artifacts made of paper (Szczepanowska and Cavaliere 2012; Szczepanowska et al. 2012).

Preservation and conservation are activities ensuring that cultural, artistic, and historic material is passed on to future generations serving as a testimony of previous generations' ways of living. Preservation and conservation activities cannot be properly implemented without understanding the physical and chemical makeup of artifacts.

Key Issues

Paper components and manufacture, an overview:
Paper can be described based on:

- Fiber composition, as rag or wood-base paper
- Manufacture, as machine or hand-made paper
- Western or Oriental, based on the geographical location of paper manufacturing and type of raw material used as paper fiber

- Sizing, based on the presence or absence of sizing as sized or unsized paper

Paper Fibers

Fibers used in papermaking are of plant origin. Commercial papers use primarily wood-origin fibers and dominate today's market, while artists' papers are made from cotton and linen (flex) fibers derived from rag; such paper is often referred to as "rag paper." The main difference is their chemical content; wood fibers contain more lignin and hemicelluloses, while cotton papers consist of nearly pure cellulose and no hemicelluloses (Rance 1980). All plants that contain lignin also contain hemicelluloses, whereas cotton and other lignin-free fibers lack hemicelluloses. Rag fibers contain the highest percentage of cellulose; thus, papers they produce are more durable and of higher quality. Because of their higher lignin content, wood-pulp papers are of lesser quality and more easily deteriorate.

Rags and later wood pulp were the main raw materials in Western papermaking. Paper made in the Far East, known as Oriental paper, utilizes mitsumata or mulberry paper (common name: kozo) fibers, harvested from the inner bark of shrubs. Paper therefore can be described as Western or Oriental, depending on the geographical location and associated type of the raw material used in its manufacture.

Cotton used for papermaking is derived from new textile cuttings, old rags, and linters. Linters are the shortest fibers in the cotton-harvested lot, varied in a range of 12–64 mm in length long and 20 μm in width. Cotton is almost pure cellulose with a small percentage of protein, pectic substances (congealed gum-like carbohydrates) ash, and wax. Characteristic twist of flattened fiber is a diagnostic morphological feature of cotton fibers.

Flax fibers are used in textile and in fine papers (rag papers). The fibers are formed in the stem of the flax plant (*Linum usitatissimum*). Chemically, flax is the same as the cotton polymer in that they are both cellulose polymers. Physically, the flax polymer differs from the cotton polymer in the degree of polymerization. Morphologically, characteristic nodules on the flax fibers serve as diagnostic feature in a microscopic examination of paper content.

Oriental Paper Fibers

Fibers of mulberry paper (common name: kozo) and mitsumata are bast fibers, and similarly to flax derive from the inner part, under the bark of plants or shrubs. These fibers are used in the Oriental handmade papers producing strong and permanent papers. Besides showing thick walls, the fibers do not have very distinctive morphological features therefore are not easily identified microscopically. Paper mulberry may show a transparent membrane in some places along the fiber wall while Mitsumata shows broader portion in the central part of the fibers (Ilvessalo-Pfaffli 1995).

Paper Manufacture

The *paper-making processes* serve as one of the broad criteria in describing paper as hand- or machine- made and laid or wove paper. The processing of paper has a direct impact on paper's longevity and susceptibility to deterioration. The principles of papermaking are essentially the same in all regions. Fibers are macerated, suspended in water, and retrieved by sieve-like mould to form a sheet. The changes in the manufacturing processes followed modernization and technical inventions in other fields. The growing needs for variations in paper's properties lead to broadening the array of additives and finishing processes.

Formation of Paper Sheets

Macerated fibers (or pulp) are suspended in water slurry. A mould is dipped into the vat of macerated pulp, and a layer of the wet, fibrous material is brought to the surface. When the paper sheet is formed on the mould made of bamboo or grass, horse hair or metal, sieve-like lattice, less fibers are gathered in areas where vertical and horizontal strains of the lattice are intersecting, thus forming so-called chain and laid lines and refer to laid paper. Wove paper is usually produced in a machine-made process and does not have chain and laid lines, but a uniform, cloth-like appearance.

Hand and machine processes produce different papers, the quality of which is determined by retention of the original features of the fibers. Long fibers are undamaged in hand processing; short fibers indicate machine production. The quality of the fibers has a direct impact on paper longevity; longer fibers,

less damaged during processing, are less susceptible to mechanical breaking and chemical and microbiological attack. The strongest and best quality papers are made by hand; the poorest are machine produced. A great variety of papers fall between these two extremes. The manual process ensures even dispersion of fibers in slurry (fibers suspension in water) and retains fibers' length, strength, and luster. Fiber flocks are almost completely avoided in a sheet (flocculation is a process in which particles aggregate into small lumps).

Paper Sizing

The purpose of adding sizing to paper is to modify its resistance to water; it is necessary for the ink to remain on the surface. Gelatin and starch were historically used as paper sizing. Gelatin is made of animal skin shavings, bone or tendon therefore is of protenacious base. Starch is a polysaccharide derived from plants. It is estimated that on a commercial level, starch sizing was abandoned ca fourteenth century in favor of gelatin (Clapp cited in James 1978). However, both are being used in individual, small production paper mills until today. For example, watercolor papers are traditionally sized, meaning additives are applied to reduce the paper sheet absorbency and making it hydrophobic (i.e., repelling water). Filter paper, such as Whatman papers, are unsized, because their purpose is to let the water freely flow during filtration processes.

Internal sizing is added to the paper pulp before it is cast in the paper mould; external sizing is applied to the paper surface after the paper has dried. Other traditional sizing included gum Arabic or rosin (Hunter 1978; Emeryton 1980). These substances bond with cellulose via hydrogen bonding and have film-forming propensity on the surface of fibers, thus modifying the paper surface.

Rosin-Alum Sizing

Alum rosin has been known and used since the nineteenth century. Rosin is a resin extracted from the pine tree, composed of several resinous acids. Alum is a salt, aluminum sulfate. A combination of rosin and alum results in production of sulfuric acid; pH drops to 4.5–5. The invention of rosin-alum sizing aimed to act as retardant of microbial and fungal growth in wet paper pulp. However, high acidity of the sizing resulted in rapid discoloration of paper and disintegration of fibers.

Causes of Paper Deterioration Paper is a stable material when properly cared for, as exemplified by archival collections of manuscript and art on paper dating several hundred years back and found in different parts of the world (James et al. 1997). However, paper can deteriorate easily when proper conditions are not met.

The causes of paper deterioration fall into three categories:

1. Inherent, contained in paper: fiber content (cellulose or lignin), introduced during manufacture, such as rosin-alum sizing or applied as acidic inks and paint, such as iron gall ink and verdigris (copper green paint).
2. Environmental, induced by exposure to environmental factors (light, humidity, temperature), contact with acidic material on exhibit or in storage enclosures, or effects of natural or man-made disasters such as floods and hurricanes, fires recovery or war conflicts. Microbiological deterioration falls into this broad category.
3. Negligence of handlers, resulting in damage, such as breakage, tearing or staining, and poor housekeeping, such as unattended pests and insects in collections.

Paper-based museum collections include not only flat sheets of paper, such as documents and art, but also bound books or pamphlets, three-dimensional objects, such as globes or papier-mâche sculptures, hats, kites, advertising balloons, and unusual objects such as large balloons carrying incendiary booms during the World War II. Those artifacts contain other materials such as wood, metal, printing inks, artistic media applied on the surface, adhesives, or other additives. Each additional material or alteration of paper dictates a different set of handling and care procedures.

Based on the paper objects' structure and nature of deterioration, two main types of deterioration can be discussed:

1. Mechanical
2. Chemical

So-called "mechanical deterioration" usually refers to physical alterations of an artifact, such as deformations (creases, folds, undulations), structural separations (tears, losses), punctures, skinning of surface, or abrasions. Mechanical type of deterioration often results from breakdown of paper on molecular level (Fig. 1).

"Chemical deterioration" indicates alterations of paper on molecular level. These changes may be induced by light (photochemical damage, as seen on Fig. 3) (Feller 1975; Feller and Johnston-Feller 1978; Feller 1994, Whitmore 2002) acidity (Figs. 4 and 5) or chemical interaction of applied additives, for example, sticky pressure tape. Bio-deterioration caused by fungi alters chemical makeup of papers that contain fillers, causes staining of paper and in conditions favorable to fungal development leads to structural disintegration of paper (Fig. 6) (Szczepanowska and Lovett 1992; Szczepanowska and Cavaliere 2000; Szczepanowska and Moomaw 1994).

Acidity is particularly detrimental to longevity of papers because even the most chemically resilient cotton fibers are weakened and destroyed by acids. Sources of acidity in paper-based museum objects can be identified as inherent, resulting from chemical alterations of paper or caused by off-gassing emitted by the most immediate environment such as enclosures (on exhibit, storage, framing) or polluted environment. The source of paper acidity may be internal, such as the high lignin content in wood-pulp papers. Lignin, an intercellular tissue of the wood, is primarily responsible for rapid degradation of papers made of wood pulp. Another source of paper acidity could be the presence of alum-rosin sizing or acidic paint. One of the visible signs of acidic deterioration of paper is yellowing and brittleness.

Preservation Principles

Preservation guidelines for paper-based artifacts in archives and museum setting are based on the understanding of the physicochemical makeup of paper, structure of artifacts made of paper, and factors which may cause deterioration of paper. The purpose for which the artifacts were collected and are used influences the preservation guidelines. Flat documents will require different handling and supports than three-dimensional globes or hats. The latter, in particular, will need supports

Paper: Preservation and Conservation, Fig. 1 Early, twentieth century photograph portrait mounted onto acidic wood-pulp board. Oval, size: 19 ¾″ × 13 ½″. (**a**) Mechanical type of deterioration manifested itself as breakage of the board and tearing of the photograph. Highly acidic and poor quality board lost its strength to support the photograph. (**b**) After conservation. The photograph was separated from the source causing deterioration, an acidic backing board. Torn fragments were assembled, aligned, and mended on reverse with Japanese tissue, as seen on Fig. 2

Paper: Preservation and Conservation, Fig. 2 Reverse of the photograph seen on Fig. 1 illustrating one of the methods used by conservators in assembling and aligning paper fragments. Once aligned, the paper fragments are mended with Japanese mulberry paper using as adhesive archival quality paste

to maintain their three-dimensional form. Preservation may be discussed in two categories as *preventive preservation* (before any deterioration occurs) and *active preservation*, such as conservation (when damage has occurred and intervention is needed).

Preventive preservation focuses on:

1. Providing proper environment for collections on exhibit and in storage. That means stable temperature (T), relative humidity (RH), and light (L) from which UV portion is filtered out. Although the values of recommended range of RH are shifting when more research reveals an intricate relationship between materials and environment, generally, according to the Smithsonian Institution, the acceptable range is from 37% to 53% (Mecklenburg et al. 2004). The most important is to avoid fluctuations of the environmental parameters (RH and T) over longer periods of time.
2. Good housekeeping, meaning ensuring insect and rodent-free environment.
3. Using acid-free materials in the construction of storage enclosures and exhibit supports. Close proximity of artifacts with these materials needs to ensure that no acidity is transferred to the original objects.
4. Handling policies, loan, transport, packing guidelines, handling and training workshops are the backbone of preventive, long-term collections care.

Conservation can be considered an active form of preservation. It requires an interaction with the objects' fabric; therefore, each step has to be carefully reviewed and planned. Any interaction with the original material leaves an irreversible mark on the original fabric; therefore, conservation should be undertaken only by trained conservators.

Knowing that acidity is detrimental to longevity of millions of archival collections, paper engineers and chemists along with archives' custodians have been engaged for years in finding solutions to prevent and retard that irreversible acidification of paper. The process of neutralizing acidity in paper is called deacidification. *Deacidification* involves introducing to paper alkaline material such as calcium or magnesium carbonates or calcium hydroxide through aqueous methods (water is the carrier) of nonaqueous (organic solvents are the carrier). Deacidification with aqueous and non-aqueous solutions has been experimented with on large quantities of books. However, there are other composite materials in books, such as bindings, adhesives, and printing media which often reacted with chemicals used in the deacidification processes; therefore, that method not always could be applied to rare and valuable collections.

Definition of conservation, according to the American Institute of Conservation reads: [*Conservation*] "The profession devoted to the preservation of cultural property for the future. Conservation activities include examination, documentation, treatment, and preventive care, supported by research and education" (AIC Directory 2012). Conservation of paper-based artifacts

Paper: Preservation and Conservation, Fig. 3 A 1948 etching on paper; artist: Milton Avery; title: "Nude with Long Torso"; size: 13″ × 16 ¼″. (**a**) Discoloration of the edges and perimeter of the image indicated, based on their pattern, contact with acidic material used by a framer. Discoloration is one of the indicators that paper became acidic. (**b**) Detail of the etching, showing impression of folds imprinted on paper. It is a typical example of acid migration by contact with inferior material. (**c**) After conservation work. Discoloration caused by migration of acids from framing material was removed in a series of treatment processes, with organic solvents, washing and chemical local reduction of stains

may involve structural repairs, minor stabilization, such as tear mending (Fig. 2) or flattening of folds, and aesthetic treatment aiming to regain visual and artistic integrity of an artifact or artwork. Decisions leading to undertaking conservation often involve input from collections

Paper: Preservation and Conservation, Fig. 4 A 1842 watercolor by D. Burgdorfer; size: 17 7/8″ × 14″. (**a**) The overall discoloration of this watercolor was caused by synergy of light effect on paper and acid migration from the backing board. The details and colors of the image were obscured by this severe discoloration. (**b**) After conservation treatment. The watercolor was separated from the board, which was one of the sources of deterioration and washed with water and organic solvents

Paper: Preservation and Conservation, Fig. 5 A detail of the watercolor shown on Fig. 4, (**a**) before and (**b**) after conservation. Through the conservation process, the original colors and details were regained

custodians/owners and curators. Conservation of spiritual collections, that is, objects that are believed to have spiritual significance or power follows rules specific to the culture that produced those artworks, objects, or documents.

Papyrology in the Greco-Roman World

Arthur Verhoogt
Department of Classical Studies, University of Michigan, Ann Arbor, MI, USA

Introduction

Papyrology, the study of day-to-day documents from the ancient world, provides a rather direct and sometimes intimate look into everyday life in the Greek and Roman Mediterranean. By studying and analyzing the documents actual people left behind, if possible in tandem with the archaeological remains, scholars can arrive at a much more detailed analysis than looking at literary texts or archaeological remains alone.

Definition

Papyrology is the field of scholarship that deals with texts written on papyrus and other perishable writing materials from the ancient world (potsherds, wood, wax tablets, linen). Papyrus was used as a writing surface from the middle of the third millennium BCE until the introduction of paper at the end of the first millennium CE.

The writing material papyrus was made from the papyrus sedge (*Cyperus papyrus*) that grew abundantly along the banks of the river Nile. The person making papyrus would take the stem of the papyrus and peel it. He would then cut strips along the length of the stem and place one layer of these strips closely together horizontally and another vertically on top. Pounding the strips resulted in bringing out the juices that would ensure the strips stayed together to form a sheet. Twenty of such sheets would be joined to form a roll. The inside of the roll would be the side where the fibers ran horizontally, the outside, vertically, allowing for easy rolling of the papyrus, without breaking it.

The writing materials that form the object of papyrological scholarship were used all over the Mediterranean world. Their organic nature,

however, has caused them to survive, with few exceptions, only in the dry sands of Egypt. Among the more notable exceptions are the carbonized papyri from Herculaneum (Italy) and Petra (Jordan), the wooden tablets from Hadrian's Wall, and a number of caches of documents found in caves in Israel (including the Dead Sea Scrolls). Potsherds with writing (*ostraca*, singular *ostracon*) have survived in bigger quantities as is witnessed by their presence on the Greek mainland and islands (Crete and Rhodes), North Africa, and elsewhere (Bagnall 2011).

Within Egypt, papyrus and other writing materials survive largely from arid, upland portions of the country. There are, for example, only a handful texts that survive from Alexandria, Egypt's capital in the Greek and Roman periods, because of the location of this city in the Nile Delta – and these only survive because they were removed from the city. Within sites at higher elevations, texts are found as part of the archaeological record in inhabited spaces and in refuse collections (Cuvigny 2009). However, texts that were found in one particular location in Egypt may derive from another location, within Egypt itself, or even in the Mediterranean world at large. Thus, there are several letters written outside of Egypt to addressees living in Egypt, often by soldiers serving in the Roman army. P.Mich. 8.490–491, for example, were written by a recruit who had just arrived in Rome, and P.Mich. 3.203 (114–116 CE) was written by a Roman soldier stationed in Pselkis in Nubia. Both men sent letters home to their family in Karanis, Egypt, where the letters from Rome were actually found during the University of Michigan excavations (the letter from Nubia was purchased on the antiquities market).

Historical Background

Papyri and other writing materials from Egypt have been the object of archaeological investigation since the early 1880s (Cuvigny 2009). Initially, papyri were the prime objective of these activities, searching for the remains of classical and early Christian texts. In the course of the twentieth century, the focus changed to papyri as part of the archaeological record in an attempt to analyze the lives of the people of Greek and Roman Egypt. In addition to this organized archaeological activity, papyri have also been discovered during clandestine excavations. These made it to the antiquities market and were purchased by the major collections in the Western world. Precise archaeological proveniences for these papyri are often unknown. Such trade has been illegal since the 1972 UNESCO Convention on the Means of Prohibiting and Preventing the Illicit Import, Export and Transfer of Ownership of Cultural Property came into force.

The writing materials from Egypt preserve all languages that were in use during Egypt's history. There are documents in the various Egyptian scripts (Hieroglyphs, Hieratic, Demotic), Aramaic, Greek, Latin, Coptic, Arabic, and smaller samples of other language communities that were present in Egypt at one time or another. Historically, the scholarly world has divided the various languages between different fields with Egyptian texts falling under Egyptology and Greek and Latin under Classical studies, often with such division that bilingual texts on the same piece of papyrus were published in separate installments. More recently, the growing interest of historical studies in the papyri from Egypt has given rise to more encompassing studies of Greek and Roman Egypt using both textual documents (whatever the language) and archaeological data (e.g., Wendrich et al. 2003).

Key Issues/Current Debates

The contents of papyrological texts are diverse and varied (Bagnall 2009). They include everything from works of literature to small receipts for the payment of taxes. The works of literature include both those that are known from the medieval manuscript tradition as well as those that were lost during that process. Among the known works, Homer is the most popular author in terms of surviving fragments, partly because of the importance of this author in education (Cribiore 2001). Among the authors whose work can now be glimpsed from papyri is Menander, as well as

several poets from the archaic period like Simonides, Sappho, and Alcaeus. Literary papyri are very important in understanding and analyzing literary culture, especially during the Roman Empire (Johnson 2010).

A large portion of the surviving texts from Egypt illustrates the activities of the state, both when Egypt was an independent kingdom under the Ptolemies and later when part of the Roman, then Byzantine Empire. There are several directives from the reigning monarchs, both decrees of the Ptolemaic kings (Lenger 1980) and edicts of the Roman emperors (Oliver 1989). More numerous are texts from the lower ranges of the bureaucracy to various higher state agencies. These include census declarations, various reports about the use of land and livestock, and so on. Taken together, papyri allow for a vivid picture of Egyptian state government at work in various historical periods. The surviving documents from Greek and Roman Egypt also include many financial documents, allowing for detailed debates about the workings of the ancient economy (Manning 2007; Rathbone 2007). There are numerous documents of sale, loan, and lease, as well as numerous accounts that allow for the reconstruction of the workings of, for example, large estates in Roman Egypt (Rathbone 1991; Hickey Forthcoming).

Although found in Egypt, papyri often illustrate matters concerning the ancient Mediterranean world at large. One text from the Michigan collection, for example, provides a list of boats that arrived at the Alexandrian harbor. The text, P. Bingen 77 (=P. Mich.inv. 5760), dates to the second century C.E. and gives a list of the boats with their tonnage, their names, the harbor from which they sailed, and their cargo (largely wine). This text gives a firsthand account of what trade in the Roman Empire was all about.

Future Directions

One of the more intriguing historical questions in dealing with Egypt's relatively rich textual sources is whether or not the arising picture is representative for other parts of the Mediterranean world. In this respect, there are two interesting tendencies in modern scholarship. The first is, for the Hellenistic period, a drive towards seeing Ptolemaic Egypt principally as a representative of Egyptian, not Hellenistic history (Manning 2010), though the everyday writing culture in Egypt may be representative for large parts of the Hellenistic world (Bagnall 2011). The second tendency is the growing awareness among historians of the Roman world that Egypt is in many (but certainly not all) respects a typical province of the empire (Lewis 1984).

Introduction

Often difficult to understand through the filter of Western thought, ancient Andean societies developed along their own unique historical trajectories that have long intrigued both professional archaeologists and the general public alike. Sometimes classified as societies without "writing," without a "State," or without "urbanism," these Andean – and in particular pre-Huari and pre-Inca – populations in fact created their own representations of the conceptual and material worlds. An abundance of archaeological evidence bears witness to the historical depth that the Andean area shares with the rest of the world. It can therefore not be confined to a "prehistory" that would only come to an end with the arrival of the Spaniards. It is from this perspective and in light of recent archaeological evidence that we will here approach Paracas culture in a way that will not reduce it to a single style of ceramic and textile crafts.

Paracas: Attempt at a Definition

On old maps from the middle of the seventeenth century, such as Johannes de Laet's, *Paracca* appears as a place name designating the desert peninsula located on the Peruvian south coast between the Pisco and Ica Valleys. *Paracas* is also the name of a wind that affects this area during the southern winter months. This name is thought to be derived from the Quechua words *para* or *paray* (rain) and *acco* or *aco* (sand): "rain of sand."

In the scholarly literature, however, the term Paracas refers to one of the most distinctive ancient Peruvian cultures. Named as Paracas after the discovery of spectacular mummies on the eponymous peninsula, this culture's area of distribution actually encompasses a large part of the southern coast of Peru (Fig. 1). This territory forms a narrow strip crossed by the rivers Cañete, Chincha, Pisco, Ica, Río Grande de Nazca, and Acarí, which flow perpendicularly to the coast, with the exception of the Ica River, whose watershed is transverse. Glacial meltwaters and torrential highland rain falls feed the coastal aquifers and rivers that flow into the Pacific.

The Paracas chronology essentially spans the period archaeologists call the Early Horizon or the Formative. The Paracas period is commonly subdivided into three epochs, namely, early (900–600 BC), middle (600–400 BC), and late Paracas (400 BC to AD 50/100).

The name "Paracas" evokes the technical and aesthetic originality of magnificent polychrome textiles and highly sophisticated ceramics (Fig. 2). The Paracas were also the creators of ingenious works of architecture – pyramids, platforms, and temples – from simple materials such as unbaked adobe bricks and hardened sedimentary clay blocks. They also left geoglyphs in the Pisco, Ica, and Palpa Valleys that predate the famous Nazca geoglyphs (0–600 AD). Another characteristic trait of Paracas culture was medical procedures, in particular cranial trepanning. Like many other Amerindian populations, they also practiced cranial deformation.

Historical Background

The initial discovery of the Paracas culture goes back to Julio Caesar Tello's archaeological work at Cerro Colorado. There, between 1925 and

Paracas, Geography and Culture of, Fig. 1 Map showing the location of the south coast of Peru

1927, Tello and his team exposed a terraced burial area with deep bottle-shaped pits in each of which multiple individuals had been buried. Tello labelled this cultural complex "Paracas Cavernas." Some individuals had been wrapped in simple cotton fabrics and were accompanied by few offerings (bowl, gourd, etc.), whereas others were accompanied by rich offerings of ceramics, pyro-engraved gourds, shells, food, etc. Bodies buried in textiles decorated with geometric motives were associated with incised polychrome ceramics, painted with postfire pigments. Paracas Cavernas burials display a type of cranial deformation known as "cuneiform" (Tello and Mejía 1979).

In 1927, Tello's excavations produced a remarkable discovery, in fact, one of the most spectacular discoveries in the history of Peruvian archaeology: the famed Paracas *fardos* (Fig. 2). From a number of collective burials at Wari Kayan, on the north flank of Cerro Colorado, facing the ocean, Tello's team recovered 429 funeral *fardos*, most of which were 1.5 m in height and 1.5 m in diameter. They are wrapped in fine polychrome textiles employing sophisticated weaving techniques and embroidered with brilliant figures, which have given rise to the name "Paracas Necropólis." These *fardos*, accompanied by diverse funerary offerings, are associated with a monochrome pottery, sometimes red or cream slipped and pumpkin-shaped that stands in contrast to the polychromy of the textiles and of Paracas Cavernas pottery. The cranial deformation is described by Tello as elongated, quasi-cylindrical (*cabeza larga*) (Tello 1959; Tello and Mejía 1979).

Conceived by Tello as two phases or two cultural groups, the terms Paracas Cavernas and Paracas Necrópolis continue to be widely used by archaeologists. However, it is necessary to bear in mind that this chronological division strictly applied to the micro-region of the peninsula and to the later part of the Paracas period. Therefore, it cannot adequately capture the

Paracas, Geography and Culture of, Fig. 2 Paracas ceramics discovered at León Dormido 3 (Photo: Balbuena); funerary bundle *fardo* Paracas Necropólis 290 (Aponte reconstruction); Paracas textile found at Animas Altas (Photo: Bachir Bacha)

spatiotemporal complexity of the Paracas. However, Tello approached material culture within its wider context, inviting other specialists (geologists, botanists, zoologists, etc.) to conduct research, thereby giving a multidisciplinary dimension to archaeology.

For specialists, another crucial chronology is the typo-stylistic Ocucaje sequence (Menzel et al. 1964), even though it is regarded as incomplete by its creators, given that it is restricted to the Ica Valley. This sequence is divided into ten phases (Ocucaje 1–10), based exclusively on the analysis of fine pottery. These objects essentially come from burial contexts, uncovered by looters, who for decades have been suppliers to both private collectors and Western museums. The lack of stratigraphic evidence demonstrating recurrent succession of the proposed phases and the absence of systematic confirmation through radiometric dating, as well as the coexistence of various phases within the same context, prevent the validation of the Ocucaje sequence for the whole of the Paracas area.

From the 1980s onward, new works began to appear that, still without shedding the notion of style, began to consider additional aspects of material culture and to extend the area of study. These were based upon fieldwork focused on changes in settlement location and organization. Eventually, some studies included radiometric dating, although in small numbers (Massey 1986; García and Pinilla 1995; Deleonardis 1997; Cook 1999).

Surveys and excavations conducted since the 2000s at various sites from Cañete to Nazca have painted a more complete picture of the Paracas culture. Supported by increasingly detailed series of scientific dates (Kaulicke et al. 2009; Dulanto 2013; Tantaleán et al. 2013; Reindel and Isla 2013) and systematic excavation of key sites, Paracas studies are no longer restricted to burial contexts and objects of "aesthetic" value according to Western canons (Bachir Bacha and Llanos 2013). Recent work has focused on territorial organization, the emergence of the "urbanism," the dynamics of inter- and extra-regional interactions, long-distance exchange, and the circulation of prestige goods (Kaulicke et al. 2009; Bachir Bacha and Llanos 2013; Balbuena 2013; Canziani 2013; Dulanto

2013). The typo-chronological narrative built around ceramics and textiles is being questioned; and the heterogeneity of material culture is approached from a perspective of social and territorial dynamics (Bachir Bacha and Llanos 2013).

Key Issues/Current Debates

Geographic Framework

The south coast of Peru, home to the development of the Paracas, is one of the driest deserts on earth with almost no rainfall. Inland life is only possible along intermittent watercourses. Because of the large, high plateaus (>1000 m), known as *tablazos*, these rivers must flow through narrow gorges across the desert, before flowing into the ocean or seeping into the groundwater and forming oases where the water table is close to the surface. Confronted with such extreme environmental conditions and hazards (El Niño, drought, earthquakes), the Paracas managed to "domesticate" this territory and adapt to the constraints of a difficult natural environment, making the most of its resources.

In the agricultural realm, people devised ingenious irrigation systems. They selected a number of useful plants (food, medicinal, textile). They wisely exploited wetland systems (*hoyas de cultivo* or *campos hundidos*, *puquiales*) and tapped into the groundwater. Their intimate knowledge of their environment led them to create a veritable "civilization" of the *huarango*. This endemic tree has many virtues: it acts as a natural fertilizer by fixing nitrogen, it can desalinize the soil, it plays a role in preventing erosion, it provides a quality hardwood and nutritious fruits, and finally its foliage provides shade in which crops can be grown, especially as it maintains a certain humidity in the ground (Beresford-Jones et al. 2009; Salomon 2013). In addition, eolian fertilization (loess) regularly regenerated the cropland (Salomon 2013).

In spite of the dry environment, agriculture thus played a vital role, supplemented by animal husbandry (camelids, guinea pigs). The valleys were home to fields where a wide variety of plants were cultivated, *pallar* (a variety of broad bean), beans, corn, peanuts, gourds, hot pepper, *chirimoya*, *pacae*, *achira*, *jíquima*, and *lúcuma*, but also cotton for the manufacture of textile fabrics. Archaeological excavations carried out at various Paracas sites have turned up a wealth of remains of these plants.

Paracas subsistence also depended on other resources. Near the coast, fogs (*garúas*) caused by the upwelling current of nutrient-rich, cold deep seawater provide vital humidity. Thanks to this current, the coast offers a diverse range of marine resources, fishing, and shellfish gathering. The periodic El Niño phenomenon causes a temporary rise of sea surface temperatures, resulting in precipitation that supports patches of vegetation. These *lomas* contain a varied flora and fauna. This ecosystem is suitable for hunting, gathering *lomas* snails and grazing camelids.

The availability of resources such as clay and mineral pigments in the surrounding mountains allowed the development of monumental architecture and the manufacture of ceramics and textiles of great technological and aesthetic diversity. Remains of all of these raw materials have been discovered in archaeological contexts, at Animas Altas/Animas Bajas in the Ica Valley also as offerings.

It is noteworthy that prestigious Paracas pottery has been found far from the heartland of its distribution, bearing witness to long-distance exchange activities. This suggests that the Paracas economy also relied on trade. This activity was apparently well developed from early Paracas times, judging by the discovery at the site of Puerto Nuevo of pottery from northern valleys (Jequetepeque, Zaña Lambayeque; Dulanto 2013). The great Chincha traders were in all likelihood the heirs of the Paracas.

The Extension of Paracas Territory

The extension of Paracas territory is subject of debate. Although its focal point remains in the Ica Valley, numerous Paracas remains – including important politico-religious centers, residential sites, and cemeteries – have come to light in the Chincha and Pisco Valleys but also in the Paracas Peninsula and in Bahía de Independencia. These discoveries demonstrate that the distribution of

Paracas material culture extends beyond its territory of origin. To the north, Paracas pottery has been found in the Topará and Cañete Valleys. To the south, fine pottery and, to a lesser extent, textiles and other materials such as rock paintings and geoglyphs displaying Paracas iconography have been found in the Palpa Valley and the Río Grande de Nazca Basin.

These findings suggest the distinction of a principal area composed of two core zones (Chincha-Pisco and Ica) from a secondary one, with two peripheral areas (Topará-Cañete to the north and Palpa-Nazca to the east and south). These peripheral areas are the interfaces, respectively, with the central coast, the adjacent highlands, and the valleys located south of Nazca.

Beyond the south coast, it is mainly fine Paracas ceramics that have been found at highland sites in Ayacucho and Huancavelica. On the central coast, its traces are found in Mala and Lima. Farther south of Palpa and Nazca, Paracas pottery fragments have been collected at sites in the Acarí Valley.

These finds are testament to the supra-regional circulation and spread of Paracas symbolism, conveyed on prestige items. These objects reflect the prestige enjoyed by the large politico-religious Paracas centers located in the coastal valleys but also economic activities linked to trade and exchange. The peripheral territories played an important role in these interactions.

Based solely on the presence of Paracas pot sherds, it seems difficult to claim a Paracas occupation, *stricto sensu* in these regions far from the core areas and their peripheries. Indeed, Paracas style items appear mixed with other styles of textiles, pottery, and architecture. Moreover architecture in the highlands generally adopts a circular form.

Paracas Settlement Patterns

The Paracas archaeological record offers proof of a settlement hierarchy indicative of social division and stratification among their occupants. This hierarchy is evident both within and across valleys. It manifests itself in settlement location, architectural size, and complexity, as well as in the nature of the material discovered there.

In terms of land use, Paracas settlements are set back from waterways, on the one hand, so as not to encroach on the alluvial plain suitable to agriculture and, on the other, to be protected from flooding.

Civic-ceremonial architecture is present from the early Paracas period. The most characteristic example is the first temple of Cerrillos (Splitstoser et al. 2010). However, the majority of remains date to the middle and late Paracas periods, pointing to significant population growth. It was the ruling elite, in constant interaction with other specialized groups, who lived at and managed these large centers.

The large pyramid complexes of Chincha (Huaca Santa Rosa, 430 m long and 25 m high) oriented east-west, at right angles to the coastline, were composed of superimposed platforms with sunken patios. Other sites (Cerro del Gentil, 70 × 30 m; El Mono, 4 m-high mounds) in the middle valley display the same type of architecture but at less impressive scales (Canziani 2013; Tantaleán et al. 2013).

In the lower Ica Valley, the archaeological complex of Animas Altas/Animas Bajas on the Pampa del Cacique extends over more than 100 ha. It consists of some 100 mounds with buildings oriented along a southeast-northwest axis (ca. 30° of deviation) and the most important up to 190 m long, 80 m wide, and 7 m high. There are several groups of monuments composed of a main pyramid overlooking a system of platforms. Between the mounds, open spaces appear to form plazas and paths. The basic architectural unit of all buildings (civic-ceremonial, residential, and/or work spaces, funerary) is the pyramid associated with enclosures, closed patios, or open plazas (Fig. 3; Bachir Bacha and Llanos 2013: Figs. 4, 13, 15, and 23). In addition, there are pyramidal buildings and high-status tombs with walls covered in carved friezes (Figs. 4 and 5). Recent excavations have revealed platforms and low terraces and roofed enclosures associated with numerous artifacts employed in domestic and productive activities (manufacture of textiles and pottery, clay figurines, jewelry; objects used in hunting, fishing, gathering, food preparation, etc.). Plazas, open and exposed spaces, suited for

feasts and public gatherings, stand in contrast to closed spaces on top of the platforms of pyramids equipped with benches and reserved for activities invisible from the outside (Bachir Bacha and Llanos 2013).

In Ocucaje, the site of Córdova (Cerro Max Uhle) appears as a complex of terraces (Fig. 6). The principal characteristic of its internal organization is the intertwining of domestic and/or work spaces with other spaces such as quarries and burial places. Judging by its material culture, Córdova may be identified as a diversified economic center initially dependent on Animas before entering the Nazca orbit.

Villages, hamlets, and necropolises, located near the ocean and on the edges of fertile valleys and interacting with the settlements cited above, were home to an essentially rural population of

Paracas, Geography and Culture of,
Fig. 7 Mounds and retaining wall at the Chucchio site (Photo: García 2010)

fishermen and probably some craftsmen. Close to the shoreline, at Bahia de Independencia, pebble retaining walls support residential terraces (Morro Quemado), while big mounds of marine waste (Chucchio) (Fig. 7) contain interconnected quadrangular rooms associated with ventilation shafts. In the desert areas that separate the coast from the valleys, a series of *conchales* (shell mounds) and shelters testify to constant communication between the two areas (García 2010).

In the Chincha Valley, extensive and dense rural settlements are found on top of the desert plateaus (*tablazos*) that dominate valleys and irrigation canals that run around them (Canziani 2013: Fig. 6). In the upper Ica Valley, steep desert slopes (Cerro Cordero, Tajahuana) reveal gridded or linear units of terraces as well as fortified villages (Williams 1980).

In the lower Ica Valley, sites of domestic character are widely distributed over flat plains. They present a number of refuse strata containing malacological remains, in particular *lomas* snails, cotton tufts, textile fragments, and grinding equipment, while their architecture, as far as visible, is restricted to modest, small structures made of clay blocks. Traces of hearths and presumably domestic pottery, as well as some diagnostic Paracas pottery, have also been found. Further south, in Palpa (Jauranga), the remains of several superimposed enclosures, built with small adobes and very solid clay walls, have been uncovered (see Fig. 5: Reindel and Isla 2013).

Architecture

At the Chincha Valley sites, adobes are predominantly corn grain or wedge shaped, whereas in the buildings of Cerrillos (upper Ica Valley), loaf-shaped adobes are the most common. However, adobes were not the only construction material used by the Paracas. The walls of the monuments at Animas were built with blocks of clay sediment extracted from quarries located at the site or in its

surroundings. These blocks are cut to a semi-rectangular shape with rounded corners. Arranged in rows, they are bound together by a mortar made from clay, straw, and sand with varying proportions; consistency and finish vary (Fig. 8). Plaster, of rustic appearance in some places and finely finished in others, covers walls, benches, and floors.

It is the retaining walls and their up to 4 m-high embankments that lend both monumentality and strength to Paracas buildings. The embankments thus define the volume of platforms and terraces. They cover up preceding structures and at the same time form the basis of new ones. At Animas, we spotted a compact embankment built essentially with sods of earth. Another one is composed of a series of intercalated layers of earth, soil clods, and plant material tied up in bundles (*totora*, corn, *grama salada*) (Fig. 8; Bachir Bacha and Llanos: Figs. 8 and 16). In some buildings the plant materials are braided and twisted into boot shapes. Some embankments have relatively thin retaining walls, thus forming some sort of compartments. Other structures such as the benches are nothing but embankments covered by thick layers of finely coated clay.

The structures of the site of Córdova were built with a unique type of retaining walls composed of structural cob made from horizontally laid bundles of twisted and folded plant stalks. Their surface was then coated with a thick but smooth layer of clay (Fig. 8).

Remains of domestic structures are rare in the archaeological record. We often find no more than the foundations of walls made of *quincha* or other perishable materials, as well as post holes. The structures of Chucchio (Bahia de Independencia de Paracas) were built with blocks of encrusted earth or saltpeter (*tierra encalichada* or *salitrosa*) mixed with seaweed (*sargasso*). Whale bones form the structural frames, whereas roofs are made of mats, sea lion skins, or reeds (García 2010).

International Perspectives, the Point of View of the Author

The dynamics of the politico-religious centers, particularly during the late Paracas period, attest to the presence of true "Andean cities" whose organization differs from Old World urbanism.

Paracas settlements were undoubtedly conditioned by environmental and technical factors as explained above, but the territory is truly a cultural and political creation. The distribution of settlements is in osmosis with their environment, and it is the sacred landscape that forms its foundation. Settlements are anchored by capturing "natural" elements (the wild) inside "the artificial," i.e., the constructed (the anthropocentric). Representative examples include the dunes that are incorporated as a natural substratum of construction into the architecture of Animas and hill flanks that form the basis of buildings at Córdova. This manner of occupying a place, far from being an expression of the naturalism that sometimes has been attributed to the pre-Hispanic world, is a symbolic act that materializes the appropriation of the territory.

The occupied space is also in a homothetic and symbolic relationship to its sacred geography. The pyramids of Animas replicate the hills that were sacred places (*huacas*), and the seemingly random orientations of buildings in fact follow "natural" features such as hills, dunes, and rivers. The landscape, socialized because it is sacred, is also an important economic resource.

The territory of Paracas politico-religious centers is not confined to their monumental cores. It also forms the heart of a network that also incorporates satellite settlements located on the valley terraces, near *lomas*, on the coast and along the roads leading to the ocean, as well as important outlier sites in other valleys or other ecological zones. The desert pampas, constantly crisscrossed and exploited in ancient times, also formed an integral part of their territory. This is evidenced by numerous remains of screens, shelters, and geoglyphs pointing toward the hills and settlements. As a result, as geographically and symbolically heterogeneous as the territory of the centers may be, it also constitutes a coherent whole whose components are articulated by notable flows of economic and symbolic exchanges.

It is also worth pointing out that the large Paracas centers are far from being dedicated exclusively to ceremonial activities. Within them, politics, religion, and economy were inextricably intertwined. The archaeological record reveals traces of ceremonies and rituals linked to the construction, renovations, and abandonment of monuments, which in some instances incorporate elite tombs (Fig. 5; Bachir Bacha and Llanos 2013: Fig. 15). These dynamics are linked to the elite's cycles of life and death. Some members of the elite turn into venerated ancestors, and it is in the monuments that the memory of the ancestors is preserved. In their construction and use, the identity of the ruling group is fashioned. The deposits could also house or be used as graves for high-ranking individuals and possibly of craftsmen, as illustrated by the tombs excavated at Animas (Bachir Bacha and Llanos 2013: Fig. 19).

The unfailing presence of offerings (including human sacrifices) in the heart of every building (at Animas) constitutes more than a propitiatory act (Bachir Bacha and Llanos 2013: Figs. 14 and 18). On the one hand, it sanctifies the foundation and renovation of buildings and at the same time justifies the transcendence of the power of the ancestors through the ruling elite. In this way, it expresses a political pact between people and land, between the rulers and the ruled.

The archaeological data collected indicates that multiple groups occupied the Paracas politico-religious centers. The "stylistic" heterogeneity of certain aspects of material culture supports this proposition. A case in point are the friezes discovered at Animas whose iconography both makes use of distinctive Paracas icons such as the *Ser Oculado* and simultaneously displays northern, Cupisnique Chavin influence in the representation of fanged felines. If this heterogeneity does not reflect diachronic change, it might have another explanation.

The iconography of the friezes could express a historic and territorial discourse. It relates both the present (Paracas icons) and the distant past, harking back to the founders, to the origins, or to a cultural heritage (icons with Cupisnique and Chavín features), both the local and neighboring

and distant lands. Fan, knife, and the flying position of the feline (Fig. 4) are elements shared by Paracas and Nazca cultures, while the "radiant face" (*cara radiante*) with darts is reminiscent of Altiplano iconography but also found on Paracas and Nazca textiles (Fig. 5). These friezes are found in the same archaeological contexts as late Paracas textiles and pottery, which in and of themselves display technological variation and "substyles."

This aspect of material culture also allows us to hypothesize that the elites of Animas had the capacity to unite diversified groups whose identities derived from professional specializations (fishermen, farmers, craftsmen, merchants), places of residence (*ayllus*, cosmogonical moieties, basins, valleys, etc.), or ethnolinguistic origins. Through diverse politico-religious strategies, Paracas leaders were able to build and reproduce sociopolitical entities and maintain sovereignty over a territory, its resources, and its inhabitants for a lengthy period of 400–500 years. The realm of the religious involves rites and ceremonies worshipping ancestors who were thought to participate through the protagonists of the rites. The religious always has a political dimension as rituals legitimize power and the order of society ruled by its elites.

Insofar as it relates historic and sociopolitical facts, Paracas iconography functions as a full-blown communication system. Its structural principles make it an ideographic writing system, often combining icons and glyphs.

Indeed, a figure may assemble heterogeneous elements, deliberately juxtaposed, sometimes superimposed, or merged. An image may blend the bodies of various animals, objects, and abstract motives (bars, circles, points, squares, etc.) or combine the human and the nonhuman (Figs. 4 and 5). There is undoubtedly a logic linking these components, and the resulting composite image has semantic value. Generally speaking, the succession of icons inserted into incised frames of Paracas pottery displays symmetry, inversion, and rupture, which suggest graphic encoding. This is amply illustrated by the iconography of Paracas Cavernas pottery (Ocucaje) (Fig. 2; see Figs. 10, 11, and 20: Balbuena 2013; Figs. 32 and 46; Menzel et al. 1964).

Future Directions

The reading of this iconography clearly remains fragmentary, and one can only comprehend general aspects of its contents. Nevertheless, primary archaeological contexts must form the basis of any attempt at interpreting its ideographic content and its intrinsic meaning. The use of comparisons, starting from the regional cultural phylum (south coast) and branching out to the Andean region and beyond, would enliven interpretation in that it would draw on the shared cultural roots of pre-Hispanic America.

Paranthropus

Ronald J. Clarke
Evolutionary Studies Institute, University of the Witwatersrand, Johannesburg, South Africa

Introduction

The genus name *Paranthropus* was created by R. Broom (1938) for a partial cranium, right mandibular corpus, and isolated teeth from Kromdraai near Sterkfontein, South Africa. The fossil had been found by a schoolboy, Gert Terblanche. Broom noted that it not only had large molars and premolars but that, if a ruler was placed across the cheekbones, the nasal region was behind the ruler. It was clear that it possessed a naturally dished face, unlike *Australopithecus* from Taung and Sterkfontein. Thus, Broom considered it a new genus of ape-man, parallel to man (*Paranthropus*), with robust jaws and teeth. He therefore gave it the species name *Paranthropus robustus*.

Key Issues/Current Debates/Definition

In 1948, Broom and his assistant, John Robinson, found similar fossils at Swartkrans Cave also near Sterkfontein and named a second species *Paranthropus crassidens*. Swartkrans proved to be a prolific source of *Paranthropus* fossils including crania (Fig. 1, right), mandibles (Fig. 2), two proximal femora, a partial pelvis, and isolated teeth. They ranged from infants to elderly and provided much information on *Paranthropus* morphology (Broom and Robinson 1952).

***Paranthropus*, Fig. 1** *Paranthropus robustus* cranium SK 48 from Swartkrans (*right*) and *Paranthropus boisei* cranium OH 5 from Olduvai (*left*), with reconstructed mandible

***Paranthropus*, Fig. 2** *Paranthropus* mandibles from Swartkrans

The dished face resulted from the cheekbones having moved forward to make space behind them for the massive temporal muscles that, in males and occasionally in females, were anchored to a sagittal crest. Such muscles were necessary to operate the heavily built mandibles that contained huge molars and premolars with low bulbous cusps that wore down to a flat surface in older individuals. By contrast, the canines and incisors were small and cramped into a small space. This emphasis on heavy grinding dentition led Robinson to advance a dietary hypothesis suggesting that *Paranthropus* was a specialized vegetarian. Because of the small size of the canines and incisors, *Paranthropus* could not have used these front teeth for tearing vegetation and opening hard fruit casings, as in the great apes. The greatly reduced size of the canines and incisors relative to the premolars facilitated the side-to-side grinding motion needed to process tough, low-quality foods, particularly at times when other preferred food sources were unavailable.

Another locality rich in *Paranthropus* fossils, including a complete female skull, was discovered by André Keyser (2000) at Drimolen Cave some distance from, but in the same general area as, Swartkrans. All of these fossils, together with a few from Cooper's Cave, Sterkfontein Caves, and

Gondolin, date to around two million years ago, and the genus continued until about 1 Ma, which is the youngest date for *Paranthropus* at Swartkrans (Gibbon et al. 2014). Associated fauna include more open grassland species than that of *Australopithecus africanus*, along with woodland and wetland species (Brain 1993). It is now generally accepted that only one South African species, *Paranthropus robustus*, is represented.

On the 17th of July 1959, Mary Leakey discovered, eroding out of Bed I deposits at Olduvai Gorge, Tanzania, a cranium with colossal cheek teeth, small cramped incisors and canines, a sagittal crest, dished face, and gutter running from the maxillary clivus into the floor of the nose (Fig. 1, left). Louis Leakey named it *Zinjanthropus boisei*, but it is clearly a massive East African form of *Paranthropus*. Phillip Tobias, who published a monograph on this cranium (Tobias 1967), did not recognize the generic distinction of *Paranthropus* and so classified the Olduvai fossil as *Australopithecus boisei*. Others before him had also considered that *Paranthropus* should be classed as *Australopithecus*. John Robinson, however, argued from his experience as both zoologist and paleontologist that because *Paranthropus* could be distinguished clearly from *Australopithecus* on both crania and postcrania, it deserved generic recognition. He was supported in this view by Clarke (1996), and now, with the very large inventory of fossils of several species of *Australopithecus* and three species of *Paranthropus*, many more researchers have accepted the generic distinction. The Olduvai cranium was given an age of 1.75 million years by potassium-argon dating of the layer in which it occurred. In subsequent years, some more fragmentary fossils, including isolated teeth of *Paranthropus boisei*, have been found in Olduvai Beds I and II.

In 1964, Kimoya Kimeu on an expedition to West Lake Natron, Tanzania, run by Richard Leakey and Glynn Isaac spotted a mandible high up in an exposure of sediments at Peninj. When he retrieved the fossil, it proved to be a *Paranthropus* in excellent condition with all teeth preserved. Particularly noticeable were the small sizes of the canines and incisors crowded in front of the huge premolars. Although similar to mandibles from Swartkrans, the Peninj jaw had teeth even bigger, of the size that would fit the Olduvai *Zinjanthropus* cranium. This mandible is classified also as *Paranthropus boisei*.

Many more fossils of this species were later recovered from similar-aged sediments on the east side of Lake Turkana (formerly Lake Rudolf), Kenya. These included some mandibles even more massive than that of Peninj, as well as crania. One magnificent cranium, KNM-ER 406, was found lying in a dry riverbed by Richard Leakey in August, 1969, i.e., 10 years after the discovery of *Zinjanthropus*. Although the teeth had been weathered away, the cranial architecture exhibited classic *Paranthropus* morphology, similar to that of *Zinjanthropus*, with a dished face, extreme postorbital constriction leaving ribs of bone above the orbits, a sagittal crest, and widely flaring zygomatic arches leaving a large space for the temporal muscles. The discovery of a smaller, less muscular cranium, KNM-ER 732, showed typical *Paranthropus* morphology and thus represented a female, contrasting greatly in size with the males KNM-ER 406 and *Zinjanthropus* (OH 5).

A partial cranium containing some well-preserved teeth including a tiny canine was found under a thorn tree at Chesowanja, near Lake Baringo, Kenya, in 1970 (Carney et al. 1971).

Beginning in 1967, several *Paranthropus* mandibular fossils and numerous isolated teeth were recovered in the Omo region of southern Ethiopia by a joint French and American expedition directed by C. Arambourg, F. C. Howell, and Y. Coppens. One very massive mandible (L7-A-125) dates between 2.15 and 2.25 million years. It is thus much older than the *Zinjanthropus* cranium or the other *Paranthropus boisei* fossils from East Lake Turkana. However, it has been generally assumed to belong to *Paranthropus boisei* (Howell 1978).

Another Omo mandible without teeth was derived from an even older horizon dating to about 2.6 million years. This mandible (Omo 18–1967-18) was made the type specimen of a new genus and species *Paraustralopithecus aethiopicus* (Arambourg and Coppens 1968). It

is now, however, classified as *Paranthropus aethiopicus*. Creation of a new species on the basis of this poorly preserved mandible was debatable, but a subsequent discovery of a cranium from West Lake Turkana provided support. The cranium KNM-WT 17000 was found in 1985 at Lomekwi and dated to 2.5 million years ago. Because of its color, it was known as the "Black Skull." Its significant differences from *Paranthropus boisei*, coupled with its early date and features shared with *A. afarensis*, prompted Kimbel et al. (1988) to place it in *Australopithecus aethiopicus* (i.e., *Paranthropus aethiopicus*). Its discoverers had considered it to be an ancestral form of *A. boisei* (i.e., *P. boisei*) (Walker et al. 1986).

Although the Black Skull has cranial architecture typical of *Paranthropus*, i.e., a broad, dished face, extreme postorbital constriction, widely flaring zygomatics, nasal gutter, inflated mastoids, wide supramastoid shelf, prominent sagittal crest, and bases of massive cheek teeth, it has some differences from *Paranthropus boisei* and *Paranthropus robustus*. The anterior dentition occupied a wide space, and the endocranial capacity was only 410 cc compared to the 530 cc of *Zinjanthropus*. The facial profile exhibits a pronounced anterior slope, contrasting with the typically much more vertical profile of *Paranthropus boisei* and *Paranthropus robustus*.

The first known cranium with associated mandible (KGA 10–525) of *Paranthropus boisei* was found in 1993 at Konso, Ethiopia (Suwa et al. 1997). The skull and eight other *Paranthropus* fossils were recovered from deposits well dated between 1.4 and 1.5 million years. They are associated with dry grassland fauna.

A very weathered maxillary fragment with damaged first and second molars (RC 911) was found in 1996 in the Chiwondo Beds of Malema in Malawi. The fossil was provisionally dated at 2.4 million years and assigned to *Paranthropus boisei* by Schrenk et al. (1997).

Paranthropus was a widespread African genus of massive-jawed ape-man extending from South Africa to Ethiopia and covering a period of 1.5 million years. It is not known outside of Africa. John Robinson had considered that the heavily built mandible of *Meganthropus* from Java was a *Paranthropus*, but the teeth are morphologically distinct from that genus, and it seems probable that it is an Asian representative of *Homo habilis*, as observed by Phillip Tobias and Ralph von Koenigswald (see "▶ *Homo habilis*").

Although *Paranthropus* has often been found in areas where there are Oldowan and Early Acheulean stone tools, it is not generally thought that *Paranthropus* was responsible for making them. *Homo habilis* and *Homo ergaster* also occur in the same areas, and it is believed that *Homo* with its much larger brain was the toolmaker, while smaller-brained *Paranthropus* relied on its specialized dentition for processing plant foods. Because of the massive teeth and jaws with associated strong musculature, *Paranthropus* is often referred to as a "robust australopithecine." This term can however be misleading because some of the so-called gracile australopithecines, i.e., members of the genus *Australopithecus*, often have large teeth and robust jaws that can exceed those of many *Paranthropus* individuals. *Australopithecus prometheus* and *Australopithecus garhi* in particular exhibit large "robust" cheek teeth.

Parchment: Preservation and Conservation

Lee G. Gonzalez and Tim J. Wess
Cardiff University, Cathays, UK

Introduction

It is believed that processed animal hides were first used as writing materials in Egypt, in the Fourth Dynasty – 2700–2500 BCE (Ryder 1964). The processed hide-parchment-grew in popularity because of the high cost and growing scarcity of papyrus. Its use spread across the empires of the Babylonians and Assyrians (2300 BCE) and is reported in inscriptions on stone tablets found from the Seleucid era (311 BCE–600 CE); KUSH-SAR appears, meaning "skin writer," and this is contrasted with DUB-SAR meaning "tablet writer."

Parchment was in many respects an ideal writing material because of the practicality of transporting parchment documents, the superior handling qualities, and its durability. It was most commonly used for sacred documents which were likely to endure much use and consultation. Although papyrus was undoubtedly the most common writing medium in the Egyptian empire, by the first century CE parchment had surpassed papyrus in popularity. Parchment sheets were often stitched together to form parchment notebooks which were used for accounts, drafts, and letters. Evidence for this use is provided by the poet Martial, who refers to the availability of parchment codices for use by travelers (Epigrams 1.2 and XIV.184–92) (Reed 1972).

Parchment documents reporting our history are culturally important; they describe – in part – the development of civilization and our progress over time. Using historical documents, we have been able to investigate the important aspects of our ancestors and the origin and attributions of divinity to humans in the ancient world. Some of the most important parchment documents ever discovered, namely, the Dead Sea Scrolls, have contributed significantly to the divine ideology.

Parchment can also provide information about how the methods of producing documents and processing animal hides have developed over the centuries. Furthermore, provenance of parchments provides information about the growth of cities, trade routes, and its economic and social importance in relation to local communities. Preserving such documents is therefore an important undertaking if we are to keep our cultural heritage intact, and parchment research is vital if we are to improve our knowledge of preservation treatments and store these precious documents for future generations.

Definition

The processing of hides into parchment involves treatments to remove a majority of the non-collagenous components such as hair and fat. The most common hides used to make parchment are those from cattle, calves, sheep, and goats. The practice of processing animal hides for the use of written documents has evolved over the last 4000 years; the main points of the manufacturing processes are well known. There are various forms of parchment, and they depend upon the manner in which the animals were killed. Most hides come from animals slaughtered in abattoirs, whereby the animal is thoroughly bled. The draining of blood allows the fine dermal blood vessels to become colorless, making them difficult to visualize in the flayed skin. If the skin is not drained of blood, the iron compounds present in the heme group react with the liming solutions and can form dark stains which are difficult to remove. If the animal has not been slaughtered in an abattoir and killed by a hunter or died of natural causes, blood often remains in the blood vessels and the parchment appears "veined," although this may not be desirable for documents, it is often used to produce decorative book bindings. Most parchments are manufactured from young animals, between 8 and 12 months old; however, occasionally much older animals may be used. The type of parchment from older animals is instantly recognizable, in that it is thick in substance.

The most revered parchments are those manufactured from kidskin and calfskin, which are made from very young animals; these are some of the finest parchments available. The skins are superior in strength and have very smooth grains. The hair follicle markings are exceptionally weak because the blood vessels have not fully developed, and their appearance is fine and hardly visible with the naked eye (Reed 1975).

The strength and durability of parchment is attributed to its main structural component collagen. Collagen is a protein made from polypeptide chains, which are linear polymeric sequences of amino acids. Collagen has a specific rigid configuration of local ordering (and in some cases long range ordering) of polypeptides chains. Collagen polypeptide chains have an obligate sequence based upon the multiple repetitive amino acid tri sequence Glycine-X-Y, where X and Y are frequently proline and hydroxyproline (imino acids). The small glycine amino acid affords the tight turn of the helical structure and its intimate relationship with two neighboring polypeptide chain sequences to form a triple helix. This metastable entity is well recognized in many tissues of the extracellular matrix. It can be described as a structural motif that polypeptide chain sequences rich in glycine and amino acids can lock into. Furthermore, the strong ropelike structure has to be perturbed significantly in order to push the local conformational stability toward a more global entropically stable state – gelatine. More detailed descriptions of collagen structures at a variety of architectural levels have been documented by Wess in (Fratzl 2008).

In skin (hide) and subsequently parchment, the fibril-forming type I and type III collagens are present. The structure of the collagen hierarchy for fibril-forming collagen types from the triple helix to the fibril and thence fiber has been widely investigated and its mechanical properties reported. Collagen polypeptide chains wind into a triple helix to form a collagen molecule, collagen molecules are then consecutively arranged to form a fibril, fibrils are arranged into bundles to form fibers, and fibers are arranged to form a collagen tissue.

The collagen triple helix is "locked" into its rope like structure. The stability of the triple helix and the collagen tissue is the result of extensive intramolecular and intermolecular bonds. The triple helical collagen molecule is stabilized by intramolecular bonding between the amide group of the glycine residues and the carboxyl group of the proline residue and water mediated hydrogen bonds. Additional stability of the collagen hierarchical assembly and aggregation of the collagen fibril is conferred to further intermolecular bonding such as cross-linking at the terminal ends of collagen molecules. There are several factors that also contribute to triple helix stability and these are well documented.

The loss of structural integrity and subsequent fragmentation of parchment are attributed to the loss of the structural order of the parchment's collagen component. When collagen molecules lose their characteristic triple helix motif, they tend to adopt a random geometry, producing a disordered structure – gelatine.

The denaturation and unfolding of the collagen triple helix post mortem requires two components: firstly, an agent to break molecular bonding and perturb the structure and secondly, water to cause osmotic swelling and force the polypeptide chains apart from one another. The agents that can cause molecular bond disruption are numerous. They include high and low pH, UV irradiation, and heat. In parchment, the measurement of degradation has been widely investigated (Gonzalez and Wess 2008).

The absence of the hierarchical structural organization and random chain conformation in gelatine means that the mechanical properties of gelatine are different to the parent collagen. The change in the mechanical properties is brought about because the random chain conformation exposes more sites for ionic and covalent molecular bonding to occur. When dry, gelatine is more resistant to deformation than the parent collagen tissue, and when wet, it has the potential to hold more water than the parent collagen tissue (Yakimets et al. 2007). This means that parchments can hold different amounts of water at the same relative humidity, depending upon their relative proportions of collagen and gelatine.

Key Issues and Future Directions

Preserving Parchment Artifacts

Archives and institutions that house parchments manage their collections to make the parchments available for use. Parchments are incredibly stable materials and when well preserved can survive for thousands of years. However, the continual problem archives face is that parchments change over time; they can, for example, discolor, fragment, tear, curl, and become brittle. The change of parchment artifacts can occur very slowly, and this can be – in part – controlled by the environment that the parchment is housed in; for example, storage rooms can have their temperature, relative humidity, and amount of light controlled. Further preservation can be enhanced by conservation treatments and the way the documents are handled (Larsen 2007). The care taken when handling documents is focused upon preventing damage as the objects are moved and read. For example, books should never be pulled from the shelf by their spine using fingernails as this could cause scratches to the covering material. It is also recommended that a hand be placed over the cover of the book and to gently slide the book forward until it can be grasped securely to remove it.

Managing the "change" of parchment collections is a difficult task because it requires a balance between making parchments available to users and protecting the integrity of the object. The array of factors that cause degradation has subsequently led to a growing need to understand how to prevent deterioration and how to store documents more effectively. The macroscopic properties of parchment have been used extensively as a qualitative means of identifying degradation of parchment. Parchment research over the last two decades has developed significantly by providing quantitative evidence of degradation within parchment; this has been through spectroscopic, thermal, and structural analysis, which has in turn informed management of collections and the effectiveness of conservation treatments (Larsen 2002). The next section provides a brief overview of how these different parchment research areas and how they have contributed to our current knowledge of parchment and the best methods for preservation.

What Do We Need to Understand to Provide the Best Preservation and Conservation for Parchments?

In the last 20–30 years, the availability of scientific techniques to the field of conservation has meant that new understandings of the parchment material and how it behaves have led to more evidence-based decisions. In this time it has been possible to work toward defining the chemical and structural changes within parchment that contribute toward the overall change of a parchment manuscript. To aid in the preservation and conservation of parchment, the following (among many) research questions can be addressed:

What Is the Structural Composition of Parchment?

Parchment as a form of treated dried skin can be analyzed using techniques that have evidenced the molecular hierarchical organization of many biological tissues. Here, the production process and subsequent storage or treatment can cause alteration in the molecular structure of the material as well as influence the differential hierarchical and stratigraphic nature of parchment. Microscopic evaluations of parchment tend to mostly be qualitative and examine textural differences within specific sites of parchment samples; electron microscopy by transmission or scanning modes also tends to have a more qualitative view of the hierarchical organization and nanostructure of fibrils being evidence or otherwise (Kautek et al. 2000). X-ray diffraction has provided a more robust way of furnishing structural information about parchment since the diffraction signal for collagen is relatively well characterized and very strong in terms of biomaterials. The intensity of the diffraction pattern and the changes that occur due to increased disorder in the sample and the presence of the lipid and mineral can all be captured in the same diffraction images (Kennedy et al. 2002). The potential to evidence the presence of gelatine in the parchment is more challenging due to the ill-defined structural basis by which gelatine is characterized as opposed to collagen. However, the ability for X-ray diffraction to collect the contribution made from several billion molecules simultaneously can provide a statistically useful qualitative analysis of the structural composition. This can be further aided by an analysis of the structural heterogeneity within the parchment from the flesh to grain side by the use of Microfocus X-ray diffraction. Typically, X-ray beams used are of the order 100–200 μm in diameter; taking thin sections of parchment samples, an X-ray beam can be used to selectively scan the parchment thin section from the flesh to grain side; this can reveal the stratigraphy of the parchment and allows the possible effects of ink penetration to be evaluated. Spectroscopy can also be used as an efficient way of examining molecular change within parchment and is especially useful where the penetration of the probing radiation such as infrared can be limited to the first few microns on the surface of an object.

How Does Parchment React with Relative Humidity?

Having defined parchment as a composite hierarchical material with a stratigraphic variation in composition and organization from flesh to grain size, it is likely that such material has a complex relationship with thermal changes and relative humidity. Although it may be attractive to imagine that parchment may behave differentially in thermal and humid settings, the quantitative evidence of this has been challenging. Thermal studies of parchment are often used to monitor the melting of collagen fibers to detect the susceptibility of parchment to be compromised by any storage or treatment strategy. Quantitative studies have been used to detect the fire damage that a parchment may have been exposed to (Fessas et al. 2000). Systematic studies where changes in relative humidity have been used to see if a lasting imprint is made on parchment have been more challenging. Few studies have been conducted in this area, and the results are difficult to interpret in terms of providing evidence regarding the best possible storage conditions for parchment documents (Hansen et al. 1992; Dernovskova et al. 1995).

What Are the Degradation Processes Within Parchment and How Can We Measure Them?

The main considerations of change in parchment are those that affect the functionality of a document, that is, the contrast with which it can be read and the ability for it to be handled. The change from

collagen to its entropically stable partner end state of gelatine leads to fragility; however, the relationship between macroscopic behavior such as cocking and tearing has been difficult to correlate causally with molecular change. Discoloration of parchment as a significant factor of change needs to be considered; although this has for some time been believed to be related to the presence of gelatine, this has more recently been shown to not be correlated to other physical changes, and the mechanism of discoloration possibly resided in more complex chemistries involving lipid and sugar residues (Gonzalez et al. 2012).

How Do Conservation Treatments Affect Parchment?

The development of intervention strategies for conservation of materials has to be approached with caution. There are several causes where strategies for conservation have caused more damage than good. Strategies for deacidification (especially in papers) and lamination of both paper and parchment have both produced unintended and damaging consequences. The potential for new developments in conservation treatment and the efficacy of established treatments can be assessed in the light of analysis of the integrity of the parchment in terms of surface and substructure. A good example is the use of X-ray diffraction to examine the potential damage through laser cleaning of parchment objects (Kennedy et al. 2004). Results showed that the collagen within parchment remained intact after laser cleaning, but parchment collagen could be damaged by exposure of laser cleaning using dwell times for cleaning longer than those advised or used routinely.

Can We Advise on a Strategy for Storage?

The scientific evidence described above can be used to inform strategies for conservation and storage. More work will have to be done in terms of longitudinal studies that will monitor and provide numerical analyses of the effects of different parchment storage environments. In terms of work conducted so far, it must once again be stressed that parchment is a stratigraphic material and that the structurally most vulnerable part of the parchment is the gelatine component and the collagen component that is predisposed to denaturation. Techniques therefore need to identify the most vulnerable parchments in collections and also be useful in identifying the region of the parchment most at risk. For example, a future phased conservation strategy may use our scientific knowledge to prioritize the parchments that have the highest gelatine content for storage under more stringent conditions and for the parchments with the highest collagen contents to be exposed to a more relaxed and cost-efficient variable RH and temperature regime.

Parker, Arthur Caswell

Chip Colwell
Editor-in-Chief, *Sapiens*, New York, USA

Basic Biographical Information

Arthur Caswell Parker (1881–1955) was the first Native American to become a professional archaeologist. He led an often contentious but ultimately successful career as an archaeologist and museologist in New York for more than five decades.

Born on the Cattaraugus Reservation in western New York, Parker firmly considered himself to be a Seneca Indian of the Iroquois (Haudenosaunee) nations. However, Parker's mother, Geneva Hortense Griswold, was originally from Connecticut and of English and Scottish ancestry. In 1879, Geneva married Arthur's father, Frederick Ely Parker, who was descended from a line of prominent Senecas, though his own mother was also Anglo. As a result, Parker's identity was ambiguous because the Seneca trace descent matrilineally while the US government traces descent patrilineally, although Parker was formally adopted into a clan and given the name Gawasowaneh in 1903.

Parker lived on the Cattaraugus Reservation until 1892, when his family moved to White Plains, a suburb of New York City. Eventually, Parker found his way to the American Museum of Natural History, where he befriended Frederic W. Putnam, then one of the luminaries of American anthropology. Parker became one of the "Putnam Boys" – which also included M. Raymond Harrington, Alanson B. Skinner, and John W. Fenton – a handpicked group of promising young students. In 1899, Parker was hired on an occasional basis at the American Museum as an "archaeological assistant." In 1903, Putnam invited him and Harrington to lead an archaeological expedition under the auspices of the Peabody Museum at Harvard University. As codirectors, Parker and Harrington productively excavated the Silverheels Site on the Cattaraugus Reservation. This experience led Parker to quit college at Dickson Seminary, to pursue a career in archaeology.

After several difficult years of temporary jobs, Parker became the first New York State archaeologist in 1906. In this role, he published widely on Iroquois ethnography (e.g., Parker 1910, 1923) but also conducted original archaeological research, focusing principally on developing a culture history of New York. Parker greatly expanded the collections of the New York State Museum and produced one of the first major scientific compendiums of the state's ancient past (Parker 1922). Parker was also involved during this period in political advocacy, campaigning for a pan-Indian nationalism, through the Society of the American Indian (Berg 2000). In 1924, Parker resigned from his state position and became the director of the Rochester City Museum. He thrived in this position, remaking the institution into the Rochester Museum of Arts and Sciences, although his administrative duties required that he reduce fieldwork and archaeological research. Parker retired in 1945, but continued writing and publishing (e.g., Parker 1952). He died in 1955, suddenly, from a heart attack.

Major Accomplishments

Although Parker did make noteworthy contributions to the archaeology of New York (Sullivan 1992), he is principally known today for his accomplishments as a museum archaeologist, a passionate advocate for scientific archaeology, and a promoter for the protection of archaeological resources. His early diorama exhibits were long considered as setting the standard for the industry, and he is credited with coining the term "museology." Parker often directly involved the public in research activities, shared the results of archaeology with the public, and published for myriad public audiences, including children (e.g., Parker 1928). Parker was also intensely involved in protecting archaeological sites, particularly from looters and casual avocational excavators (e.g., Parker 1938).

Parker's other major accomplishment was his novel ability, as a self-identified Native American, to have a fruitful career in archaeology during a period in which few ethnic minorities could participate in the sciences. Despite the bias and bigotry he faced, Parker reached some of the highest offices in the field: Parker served as vice president of the American Association of Museums (1927) and president of the New York State Archaeological Association (1932), Society for American Archaeology (1935), and New York State Historical Association (1945). He became a fellow of the Royal Society of Arts and also the American Association for the Advancement of Science and received numerous awards and honorary degrees. Parker's successes as a professional archaeologist demonstrated more than a century ago that Native Americans could contribute, significantly, to the field.

P

Parks Canada: Historical Archaeology

E. Gwyn Langemann
Archaeology and History Branch, Indigenous Affairs and Cultural Heritage Directorate, Parks Canada Agency, Calgary, AB, Canada

State of Knowledge and Current Debates

Parks Canada Agency is the primary institution conducting historical and underwater archaeology

E. Gwyn Langemann has retired.

in Canada. It has been honored by the Society for Historical Archaeology for single-handedly establishing the discipline of historical archaeology for an entire nation. Parks Canada is the federal government agency responsible for the extensive system of national parks (NP), national historic sites (NHS), and national marine conservation areas throughout Canada. Historical archaeological research, on land and underwater, supports cultural resource management (CRM) and interpretation at historic sites within the national parks and at operating NHS. Parks Canada is the operational arm of the Historic Sites and Monuments Board of Canada (HSMBC), the federal advisory board responsible for identifying places, persons, and events of national historic significance.

This survey looks at the development of a historical archaeology program in Parks Canada and highlights projects that have taken place across the country. It considers the challenges that face a national program in such an extensive country, where archaeology takes place in the context of developing and managing a system of national historic sites and national parks, and considers the way in which archaeology has integrated Indigenous participation.

The first national park in Canada, now known as Banff, was established in 1885 and the first NHS at Fort Anne in Nova Scotia in 1917. With the creation of the Dominion Parks Branch in 1911, Canada was the first country to establish an agency devoted to managing its system of national parks. In the 1960s, a growing public interest in matters of archaeology and heritage led to the passage of legislation in all provinces and territories regarding heritage preservation. Archaeological sites within the federally owned national parks and NHS, however, remain outside of provincial and territorial jurisdiction and are the responsibility of Parks Canada. There is no overriding national archaeology legislation. In the more recent national park reserves in the northern territories and on the Pacific coast, established under the modern Indigenous treaty process, archaeological sites and artefacts are often managed in a formal cooperative manner with the First Nations. Matters of cultural heritage and archaeology are explicitly covered in many of the modern treaties. NHS may also be UNESCO World Heritage Sites, so there can be many layers of significance and mandate responsibility at an archaeological site.

A Parks Canada historical archaeology unit was set up in Ottawa in 1961, to inform an ambitious program of restoration and reconstruction at national historic sites such as the eighteenth-century Fortress of Louisbourg in Nova Scotia. By the early 1980s, separate archaeological units were established in regional offices, where archaeologists had wide-ranging responsibility for both historical and precontact archaeology, in both the national parks and the NHS. In 2012, a much-reduced archaeological staff was again centralized in the national office. Today, the majority of fieldwork is done by contract archaeologists, and Parks archaeologists are developing a regulatory and reviewing role for themselves. A separate marine archaeology unit has a primary focus on historic wrecks and still maintains a strong field research program.

Parks Canada also has a strong national presence in precontact period archaeology, and often the line between historical and precontact archaeology is not clear. This is particularly true in parks established under modern Indigenous treaty provisions, where traditional land use continues, and CRM is a joint responsibility with First Nations. In all the national parks, archaeology is integrated with an array of resource management interests. Human presence in the landscape and human resource use is understood as one component of an ongoing ecological relationship; historic sites are only the most recent layer. In some northern parks, the management plan explicitly says that there can be no ecological integrity without the ongoing presence of people and their traditional practices.

Parks Canada archaeologists have the advantage of being part of a larger agency. Archaeological evidence is just one part of the team effort needed to pull off the successful restoration or reconstruction of an historic structure. Within Parks, an archaeologist has the opportunity to work in a sustained relationship with colleagues who are historians, conservators, or skilled tradesmen with experience in restoring historic masonry

Parks Canada: Historical Archaeology, Fig. 1 View along the top of a series of newly re-pointed masonry piers that supported the original 1885 Canadian Pacific Railway track high above the Illecillewaet River, on the approach to Rogers Pass in Glacier NP. The elevated grade lengthened the approach in a series of loops, allowing a more gradual grade on the steep approach to the summit. In order to avoid the avalanche dangers at the pass, the Connaught tunnel was built in 1919, and the aboveground grade abandoned. (Parks Canada, J. Porter, 411 T-28E)

(Fig. 1) or log structures or the masonry of historic canal and lock systems. A restoration architecture unit is part of the cultural heritage team based at the Winnipeg office. Parks archaeologists also have the opportunity to work with their colleagues in the national parks or NHS, who are charged with the operational responsibilities of preserving and interpreting the archaeological sites for the public benefit and for the long term. The opportunity to work on an archaeological site for many years, to get a thorough understanding of it, and to know that you are contributing to its preservation is seldom found in the consulting archaeology world. Similarly, there is the opportunity to work in a park for a sustained period and gain a deep understanding of the patterns left by people moving in the landscape over time, on a regional basis.

The challenges facing Parks Canada archaeologists today come from many directions. The network of protected areas is extensive, and parks and sites are found in every possible ecological setting. The logistics of getting to a remote site and mounting a field project can be daunting. Sites are being damaged by melting permafrost, shoreline erosion, catastrophic floods and rock falls in the mountains, wildfire, the pressure of infrastructure developments, and the ongoing impact of severe Canadian weather. Budgets and changing government priorities are always an issue. There are always questions of triage in such an extensive system. Archaeological work that focuses on salvage and preservation may take priority over a research project, but sometimes even salvage work is left undone at one site because of an urgent need elsewhere.

The historic sites managed by Parks Canada include such a wide variety of site types, from so many time periods, that it is difficult to make any summary statements. Canada is a very large country. Historic sites range from the bleak stone fortress at Prince of Wales Fort on the tundra shore of Hudson Bay, the wooden shacks used by Arctic explorers at Fort Conger on Ellesmere Island, and the gold rush towns in the Yukon, to the early farmsteads at Point Pelee NP in the southernmost point of Canada. The Maritime Provinces in Atlantic Canada have a large number of military sites related to the colonial battles between France and England and the later conflicts with America in the War of 1812. Historic sites in southern Ontario and Québec relate to the early settlement and industrial development of Canada, including

extensive canal and lock systems, and include major complexes of urban fortifications and housing such as the Fortifications of Québec NHS. Fur trade forts, coal mines, ranches, and farmsteads are found in the Prairie Provinces. Fisgard Lighthouse and Fort Rodd Hill NHS are on the southern tip of Vancouver Island, a naval establishment that guarded Victoria and the Pacific coast right up to the Second World War. The large national parks in the western provinces, including the contiguous block of four parks in the Rocky Mountains (Banff, Jasper, Yoho, and Kootenay), contain many small historic sites related to early railway exploration, mining (Fig. 2), and logging. These parks were established early in the history of Canada as a nation, before there was much settlement, and so the archaeological emphasis in these extensive parks has been on the precontact period. There are fewer and smaller national parks in Eastern Canada, and most of these were established long after the areas had been settled, so they include the remains of established farms and industrial activities within the modern park boundaries. In Eastern Canada, the archaeological emphasis has been on historical projects. In the new parks in Northern Canada, established within the treaty process, the boundary between historical and precontact archaeology is blurred indeed, and archaeologists work with the Indigenous community to record archaeological and traditional use sites.

Like any federal department, Parks Canada has lived through periods of expansion and generous funding and periods of restraint and challenge. Parks Canada has been housed in a number of ministries, including Indian and Northern Affairs, Canadian Heritage, and Environment. Currently, it is housed in Environment and Climate Change Canada and has a strong mandate for fostering Indigenous relationships. The larger mandate of the ministry has some impact on the nature and scale of the archaeological projects that Parks Canada is able to implement. Parks, however, has always had a strong sense of its core values, rooted in the physical reality of the parks it is entrusted with. The department is referred to as "Parks Canada" throughout this review, although the formal name of the agency has changed over time.

First Phase: Applied Archaeology on Big Reconstruction Projects

There have been three main phases in the practice of historical archaeology within Parks Canada. First, a dedicated unit was based in Ottawa to

Parks Canada: Historical Archaeology, Fig. 2 A cabin structure at the hard rock mine adits at the tree line on Protection Mountain, high above Lake Louise in Banff NP. The mines are from the early 1880s (Parks Canada, G. Langemann, 124R-26E)

practice applied research, to be the handmaid of historians in the reconstruction and furnishing of historic sites where the public could experience living history. Second, a much expanded archaeological staff and conservation laboratory capability was spread across the country in regional offices, practicing historic and precontact archaeology and providing CRM and interpretive advice as needed. A dedicated historical material culture research unit was maintained in Ottawa, but they did little fieldwork. Third, the archaeological staff has recently been reduced to a largely review and advisory presence in the regional offices, and the current plan is to centralize all of the lab and collections facilities.

At the beginning of the formal archaeological program in Parks Canada, historical archaeology was quite deliberately separated from precontact period archaeology. Organizationally, archaeology has always been housed in the National Historic Sites Directorate within Parks Canada, rather than in the National Parks Directorate. Practically, this separation became less meaningful over time, particularly when site inventories in the large western and northern national parks recorded thousands of archaeological sites representing a 13,000-year span of time. In 1961, however, Parks Canada felt that the expertise needed for precontact archaeology could be found in the university departments, and much of the early survey work in the large national parks of the west and the Rocky Mountains was in fact done by academic archaeologists (Langemann 2011). An expertise in historical archaeology was not so readily available in Canada, and so a dedicated unit was formed within Parks Canada, with a mission-oriented focus (Swannack 1975; Rick 1970).

The HSMBC was formed in 1919. The early historic site commemorations were chosen by the Board to promote moral values of patriotism and duty and to mark the birth of a nation; they focused on themes of French and English settlement, the loyalist defense of Upper Canada from American invasion, discovery and exploration, and the advancement of science. In Western Canada, fur trade posts and Treaty signing sites were chosen, because they fit the exploration theme and marked the expansion of the geopolitical boundaries of Canada. The HSMBC concerned itself with identifying geographical locations and marking them with formal cairns and plaques but did not investigate them further. An interest in developing the historic sites for heritage interpretation emerged in the 1950s (Taylor 1990; Klimko 1998). This was the result of several factors, including a growing sense of national pride and identity, a booming post-war economy, and the recommendations of the Massey Commission in 1951 about federal measures that could promote a unifying sense of Canadian culture. At the same time, there was an emerging sense that the regional interests needed to be better represented and a vocal interest in preserving examples of regional architectural heritage. The practical implementation of this greater federal emphasis on interpretation and architectural preservation fell to the HSMBC and to the Parks Branch that was charged with implementing the recommendations of the HSMBC. J. D. Herbert became Head of Research in the National Parks and Historic Sites Division in 1959, and he came from a background of archaeological work at fur trade sites in Saskatchewan and at Rocky Mountain House in Alberta. Herbert promoted the concept of living museums, where posts were reconstructed exactly as they were at a given point in time. To achieve this goal, archaeology was needed to fill in the gaps of a history that never could provide those small, telling details.

Historical archaeology at Parks Canada began in 1961, when Herbert created a staff archaeologist position in the National Historic Sites Service, filled by John Rick. Rick then built up an archaeological staff in Ottawa to fill the need for the applied research behind an ambitious program of restoration and interpretive project in an expanding NHS system. A separate Fortress of Louisbourg restoration section was also created to support the monumental reconstruction of the eighteenth-century fortified townsite and port as it would have been in the 1740s (Fry 1984). From its origin in 1713, Louisbourg served as an important fishing port for the French. The townsite and harbor were fortified at enormous expense and guarded the entrance to the St. Lawrence River and the colonies of New France. The Fortress of

Louisbourg changed hands several times in the eighteenth-century battles between French and English, before its capture and demolition by the English in 1758. Louisbourg remains the most extensive reconstruction project that Parks ever undertook, and Louisbourg is still the only NHS with its own archaeological lab and collections facility.

Canada's centennial in 1967 was a time of optimism and economic growth. This was a time of big projects that lasted for years, in both federal and provincial heritage programs. The visual impact of a big historic reconstruction allowed the visitor to feel a strong emotional connection to the tangible past. Many of the sites were chosen for development not necessarily because they were the most historically significant sites but taking into account the advice of regional heritage groups and the needs of local politics. The excavation and restoration projects of the 1960s and 1970s were at NHS across the country, chosen to reinforce national identity, create employment in the regions, and support a historical narrative of social and economic progress (Klimko 1998). For example, Castle Hill, the Halifax Citadel, Fort Beausejour, and Fort Lennox spoke to the battles of the colonial period between the French and English. Les Forges du Saint-Maurice spoke to early industrial history and Fort Wellington to the War of 1812. Lower Fort Garry, Rocky Mountain House, and Fort Langley (Fig. 3) spoke to the expansion of the fur trade into Western Canada. The Nuu-chah-nulth village of Yuquot on Vancouver Island spoke to the first contacts between Captain Cook and a thriving First Nation in the late 1700s. The excavations at L'Anse aux Meadows on the northern tip of the island of Newfoundland confirmed the presence of a gateway Viking settlement dating to 1000 AD (Wallace 2006).

These big restoration projects firmly established the requirement for archaeology as part of any NHS development team. Archaeologists were needed for the excavations but also to work directly with engineers and architects and to catalogue and analyze the vast piles of artefacts that resulted. A full-time archaeology team meant that thoughtful reports could be written, and the time could be taken to develop an expertise in historic sources and material culture relevant to each site.

The team of historic archaeologists rapidly developed research skills and material cultural expertise that were not found elsewhere in the country. An authentic reconstruction demanded a detailed level of knowledge; these were not meant to be generic sites but sites that were furnished and interpreted in as accurate and authentic a manner as possible for a chosen time period, based on the specific archaeological evidence. As excavations proceeded, a reference collection of artefacts for material culture research was established in Ottawa, and identification manuals were published that became standards in the field. Specialist researchers published on items as diverse as glass trade beads (Karklins 1985), trade goods used as ornamentation by Indigenous people (Karklins 1992), shoes, china, lighting devices, gun parts, military headgear, and glass (Jones and Sullivan 1989). Archaeological research also provided an understanding of the buildings themselves, both the construction techniques used, and the evolution of domestic and military structures over time. Even though managers in Ottawa saw the historical archaeology as mission-oriented applied research, the archaeologists managed to undertake problem-oriented work as well. This was the time of the new processual archaeology; archaeologists were trying to answer questions about the dynamics of social relationships within the barracks, as well as discovering the architectural details and recovering enough artefacts for the interpretive displays.

Second Phase, Regional Offices and Cultural Resource Management

By the early 1980s, responding to the wide regional scale of work, specialist archaeological, curatorial, and conservation staff were stationed not only in the national capital at Ottawa and Gatineau but also in the four regional service centers and at the Fortress of Louisbourg NHS. The service center offices housed a variety of professional and technical staff that served the national parks and national historic sites in

Parks Canada: Historical Archaeology, Fig. 3 Fort Langley NHS. All buildings are reconstructions except for the white structure on the left which is the only original building at the site (a storehouse from the 1840s). Archaeological excavation was done at each location before rebuilding. (Parks Canada, J. Porter, 2 T-234E)

Western and Northern Canada (out of offices in Vancouver, Victoria, Calgary, and Winnipeg), in Ontario (out of Cornwall), in Québec (out of Québec City), and the Atlantic provinces (out of Halifax).

However, the 1980s was a time of economic contraction, and the era of big reconstruction projects was ending. Instead, Parks Canada responded to the same growing public interest in matters of heritage conservation that had led to new provincial legislation across the country, beginning with the *Alberta Heritage Act* in 1970, and to a corresponding increase in CRM consulting archaeologists needed to address the legislative requirements. In Parks Canada too, archaeologists were responsible for carrying out an expanded range of archaeological heritage resource management needs. They did primary survey, impact assessment and CRM work, research excavations, and public presentation, for both precontact and historic sites. The regional offices were the repositories for artefacts and records, and artefact reference collections were established from work in the local parks, including precontact artefacts and lithic type collections. These were used by academic and consulting archaeologists.

Since the days of the large historic restoration projects, NHS commemoration has changed in emphasis from reconstructing buildings as the centerpiece of a relict landscape, frozen at one point in historic time, to valuing structures and artefacts for their witness to the evolution of a cultural landscape over time. This changed along with the recognition that archaeological and historical data and interpretations are not inherently value-free and neutral and that there must be room in a site presentation and interpretation for multiple points of view.

In 1992, Parks Canada formalized an innovative CRM Policy. Recognizing that there were phases of evolution over time represented at a national historic site, the CRM Policy asked historians and archaeologists to determine whether the resources (artefacts, structures, features, elements of the natural setting of the site) were directly related to the reason the site was commemorated as being of national significance, in which case they were assigned a Level 1 value. Resources not directly related were Level 2; these were still of archaeological or historic value and may even be of high regional or local value, but if push came to shove, they received less attention than the Level 1 resources. A team of park operational managers, archaeologists, historians, and architectural specialists came together to consider all the resources at a NHS thoughtfully, to determine their value and to write a Commemorative Integrity Statement spelling out the factors that defined the heritage character of each NHS and the actions needed to preserve and to promote

them. The CIS provided direction for archaeological research and for management actions.

If the story of designation, development, and management of any particular NHS is considered over time, it will have responded to changing views about what is appropriate. For example, Fort Walsh NHS in the Cypress Hills of southwest Saskatchewan was designated for its importance as the North-West Mounted Police headquarters in the 1870s and the role it played in bringing the rule of law to the west. But there are also structures and archaeological remains present at the site relating to precontact use, to the American whisky traders that the Mounties suppressed, to a massacre of Indigenous people by some of these traders, to the encampment of Sitting Bull and the Lakota who sought refuge in Canada in 1876 after the Little Bighorn, and to later ranching in the area after the Mounties left. If the parks policy of earlier days had been followed to the letter, the structures from all these secondary themes would have been at best ignored, and at worst destroyed, and only the NWMP fort preserved. Today, archaeologists have investigated all these other themes, and their interpretation is an integral part of telling the complete Fort Walsh NHS story. Recent archaeological work has used ground-penetrating radar to survey palisade lines at the whisky trading post and features at the NWMP cemetery. Sometimes it is a good thing that Parks Canada is chronically short of the funds and staff needed to fully implement their policy.

New Park Establishment and Baseline Inventory

Parks Canada has a systems plan to guide the establishment of new national parks, with the goal of ensuring that all ecological regions in the country will eventually be represented by a protected area. As new national parks are added to the national parks system, funds are made available for an inventory of the archaeological sites, in the same way that baseline inventories are made of the natural resources. Historic and precontact sites are dealt with together in such work. For example, in the 1990s, surveys in Grasslands NP in southern Saskatchewan recorded hundreds of stone tipi circles and bison drive lane features but also historic ranching settlement features such as barns dug into the creek banks. Gwaii Haanas National Park Reserve is jointly managed with the Haida Nation. New park establishment surveys identified a wide range of sites, from cave sites from the early postglacial period to village midden sites along the intricate coastline. The protected area at Gwaii Haanas includes a marine component, and the historic sites inventory includes many shipwreck sites. Efforts have also been made to identify early archaeological sites that were submerged by rising postglacial sea levels.

National historic sites are also brought into the Parks Canada system according to a plan and on the recommendation of the HSMBC. In the early years of the national historic sites program, most sites were considered individually or opportunistically. Later, the HSMBC considered thematic groups of commemorations, based on comprehensive historical research papers, and sites were brought into the system to represent themes such as the prairie settlement patterns of different ethnic communities, industrial and mining sites, or significant precontact period archaeological sites such as Head-Smashed-In Buffalo Jump in Southern Alberta. Over the last 20 years, there has been an emphasis on bringing in sites that speak to Indigenous history and values, the experience of different ethno-cultural communities, and women's history. Nominations for these sites come out of a program of community consultations and workshops.

Where the newly designated sites are owned and operated by Parks Canada as a national historic site, a baseline archaeological inventory is made, and archaeological excavation is done as needed during the process of building restoration and construction of interpretive facilities for the public. For example, the Bar U Ranch NHS in the Southern Alberta foothills came into the system in the early 1990s. A complex of wooden structures on sandstone footings all needed to be lifted before restoration could take place. Archaeology was done at each structure, by Parks Canada archaeologists (Fig. 4), and as part of a university

Parks Canada: Historical Archaeology, Fig. 4 The 2008 excavation in the collapsed root cellar of the Bar U Ranch NHS, before it was reconstructed. (Parks Canada, uncatalogued photo, W. Perry)

archaeological field school. Some of this work was explicitly a public archaeology program, and the excavations were built into the daily program of school tours and public interpretation offered by the Bar U Ranch staff.

At the Bar U Ranch NHS, precontact sites were also found and excavated. It is often the case that historic structures are built on top of precontact sites; many of the same features that made a location desirable for Indigenous use made it attractive to settlers. In the early days of the historical archaeology program, the historic structures alone were the focus of the excavations. For example, the 1970s excavations of the late eighteenth century and early nineteenth-century fur trade forts at Rocky Mountain House NHS went down to the base of the wooden palisade walls and cellar features and no further. Recent pipeline impact assessment work at Rocky Mountain House NHS has discovered 5000-year-old precontact period sites, more deeply buried than the base of the historic features. Today, an archaeologist working at a historic site would make sure that the ground was tested to the base of the postglacial soil deposits, so that any earlier phases of use of the area were found. The whole story of human use of an area over time is important; we cannot assume we know everything about a site just because there has been historic archaeological work done in the past.

Cultural landscapes are an important part of archaeological interpretation today. Structures and artefacts are important on their own but also as part of a pattern of landscape use. The distribution of sites over the landscape and how those patterns have changed over time, the ways in which human use has altered the physical landscape, or the plant and animal resources present have created cultural landscapes. The elements that define the heritage character of a national historic site often include such things as archaeological features that bear witness to the evolution of a site over time or to less tangible things such as the viewscapes and surrounding vegetation. Some NHS have been commemorated entirely based on their cultural and spiritual significance to an Aboriginal community. For example, the Sahoyue-Edacho or Scented Grass Hills and Grizzly Bear Mountain NHS on Great Bear Lake in the Northwest Territories is commemorated as an associative cultural landscape. Here, landscape features embody the history of the Sahtugotine Dene people as a mnemonic device; each time someone travels the trails and recites the stories that are linked to particular landscape features, the culture history is reinforced and transmitted. The land is alive with stories that blend

the natural and spiritual worlds. How does the work of an archaeologist help with this kind of a historic site? It can record the physical traces left by people using the trail over the millennia, at the established campsites along the way, but there is little that the usual archaeological practice can do to identify the intangible associative values. Archaeologists must use their anthropological skills here, the skills of listening to community members, of being out on the land in their company, of transcribing oral history, and of linking human actions to traces and features on the landscape. These skills are applicable to both historical and precontact archaeology and to working with modern communities whether Indigenous communities that preserve a traditional ecological knowledge or the descendants of settlers who brought their own traditions to a new world.

Rouge National Urban Park is currently being established in the Rouge River watershed within the greater Toronto area, providing a national park experience for Canada's largest metropolitan area. Within the park boundaries, there are working farms as well as a rare example of the Carolinian forest in what is otherwise a heavily industrialized and settled area. Previous archaeological work here has been done under provincial regulation, and a variety of precontact period and historic sites have been recorded. Here, there has not so far been funding for a new park-wide survey, but the provincial site registry is being consulted and the existing information entered into the parks system. Parks Canada archaeologists are currently doing an impact assessment for the parks Welcome Centre, which is being built at the former site of a mid-nineteenth-century post office in the small settlement of Mongolia.

The new park establishment program has funded some excellent and extensive archaeological inventory and research excavation projects. One consequence of that, because there is only so much money, is that field and research work in the already established parks and sites can be neglected. Park managers may consider that the archaeology has been "done" at the established sites, that the history is well understood, and that there is no need for further work. Research marches on, however, and our understanding evolves. Historians find new documents that show our previous understanding of a historic site to be incomplete or mistaken, and the discipline of history develops new approaches and insights, as does archaeology. History is not something you do once and then it's done. Neither is the historic archaeology that works hand in hand with historic research. For example, the extensive archaeology backing the restoration project in the 1970s at Ft. Beauséjour, in New Brunswick on the Bay of Fundy, was geared to understanding its development as a French fort in the colonial wars, up to 1758. The fort was rebuilt and renamed as Fort Cumberland by the British and played a role repelling American troops in 1776, but there has been little research on the features related to that period or to the evolution of the whole site over time. At Fort Gaspareaux in New Brunswick, which has not been reconstructed and is purely an archaeological site, it was recently discovered that management actions have been based on a misreading of the document plans of the site. It had always been assumed there were no resources left on the east side of the fort, but shore erosion has exposed archaeological remains, and it is now clear that the management approach has unwittingly left the archaeological resources exposed and uninvestigated.

Visitor Experience, Public Education, Site Salvage, and Ecological Restoration

Historical archaeology projects emphasize visitor experience and public education, as well as research. An excavation under the Dufferin Terrace, in the heart of the World Heritage district near the Québec Citadel, exposed the Saint-Louis Forts and Châteaux, the seat of the colonial governors between 1620 and 1834. This was a highly visible excavation, in progress during the 400th anniversary celebration of the founding of Québec City in 2008, and visitors came in their thousands. Today visitors walk through the stabilized foundations in a crypt exhibit below the restored boardwalk of the Dufferin Terrace. Public archaeology projects have run for several years at the Acadian farmsteads of Beaubassin, at Louisbourg, and at the fur trade forts of Rocky Mountain House.

Sometimes it is impossible for visitors to come to a site. A 3D laser scan of the entire site of Fort Conger NHS, at the northern tip of Ellesmere Island in Quttinirpaaq NP, provided a detailed virtual rendering, so the public can experience an otherwise inaccessible site. The scan also provided a baseline recording for scientific and management purposes and provided an opportunity for the University of Calgary archaeologists to refine the laser scan technology (Fig. 5). This site has intermingled remains of multiple occupations from British and American exploration parties in the heroic age of north polar exploration in the late nineteenth century, as well as twentieth-century Canadian, British, and Danish expeditions. The structures include huts built by Admiral Peary's party in 1900, to a design influenced by the northwest Greenland Inughuit members of the party. Construction of the huts used remnants of a station originally constructed by Lieutenant Adolphus Greely in 1881 to house the Lady Franklin Bay Expedition, making scientific observations for the First International Polar Year of 1882–1883.

Work at historic sites is often salvage in nature, responding to threats of erosion from changes in sea level on subsiding coastlines (e.g., at the Fortress of Louisbourg) or from melting permafrost and riverbank erosion (York Factory and Prince of Wales Fort on Hudson Bay). In a country with as much coastline as Canada, shoreline erosion is a major problem. York Factory was used by the Hudson's Bay Company as the principal northern fur trade depot between 1684 and 1957, the shipping gateway to all of Rupert's Land at the mouth of the Hayes and Nelson Rivers on Hudson Bay, in Northern Manitoba. There have been many successive phases of building here, including an early stone and brick fortification, but this construction method did not last well in the permafrost, and later structures were wood. Regular monitoring shows that the Hayes riverbank is receding at 0.5 m a year, with localized recessions that are much deeper. This is having a severe impact on archaeological structures and features, and recent archaeology programs have focused on the complex of drainage features between the still-standing main wooden depot structure and the shoreline, in the area most immediately threatened. Drainage and erosion have always been an issue at York Factory, and the same natural processes that the original inhabitants had to deal with are now threatening the survival of the site. This is accelerated by warming and melting permafrost, and the park is evaluating measures such as installing insulation below the historic

Parks Canada: Historical Archaeology, Fig. 5 Still from the 3D laser survey of Fort Conger NHS, showing the remains of the 1881 station built by Greely to house the Lady Franklin Bay Expedition on Ellesmere Island, Quttinirpaaq National Park. structures to preserve the ice floor. Ultimately, however, this and many other sites along the Arctic shoreline are severely threatened, and a series of salvage excavations may be the only possible answer. But choosing which of the many threatened sites can be adequately salvaged is an unwelcome and difficult exercise.

The nearby Prince of Wales Fort NHS at Churchill, on the shore of Hudson Bay, is a star-shaped stone fort built on the tundra by the Hudson's Bay Company between 1731 and 1771, a time of conflict between France and England. The masonry walls are 4 m thick and still support a battery of cannons. The integrity of the masonry is severely threatened by freeze-thaw cycles, melting permafrost, and water infiltration. Archaeological excavations have taken place to aid in understanding the original construction, as an impact assessment before modern drainage measures were installed, and to inform a multi-year maintenance program, as well as to provide an understanding of the material culture and human life at the fort.

A recent example of historic archaeology responding to coastal erosion is the salvage in 2016 by Parks Canada archaeologists of graves that were eroding into the St Lawrence River, on the Cap-des-Rosiers, in Forillon NP. The graves are presumed to be those of Irish immigrants travelling on the *Carricks*, shipwrecked off the Gaspė coast in 1847, and physical anthropological work by the University of Montreal supports this interpretation. The tragic incident has a vivid place in the oral history of the Gaspė inhabitants. The archaeological work was linked to an ecological restoration project, designed to protect the beach at Cap-des-Rosiers.

Precontact archaeological research has contributed to the ecological restoration goals of the national parks. For example, zooarchaeological research in Banff and Waterton Lakes NPs has contributed to our understanding of the distribution and population structure of bison in the past, as park managers restore bison to the landscape (Langemann 2004). For an extirpated species, analysis of the remains of bison in dated archaeological contexts provides one avenue to understanding their past distribution, diet, population structure, and the way in which humans have used them over time (Fig. 6). Excavation of a garbage disposal pit at Jasper House NHS, a fur trade post that supplied the Columbia district, uncovered a large sample of butchered mountain sheep bones, including dozens of mandibles. Not only could these speak to the diet of the fur traders but they also have zoological value. They provide a sample of a single population from a narrow moment in

Parks Canada: Historical Archaeology, Fig. 6 The damage done by a spring flood at Pekisko Creek in the middle of the Bar U Ranch NHS. In 2 days, the high water carved a new bend 100 m back from the previous channel edge, exposing a bison kill and processing site in the north pasture. (Parks Canada, B. Himour, 1670R-593E)

time before the wildlife in the Athabasca River valley were extensively disturbed by settlement. Samples of elk bone from both precontact and historic archaeological contexts in Alberta were used in a mtDNA genetic diversity study, designed to aid modern wildlife managers by establishing the distribution of elk subspecies in the past (Speller et al. 2014).

Historical archaeological sites can also play a role in understanding landscape change. Between 2013 and 2016, an archaeological survey of logging features in La Mauricie NP, between Montreal and Québec City, took place as part of a project to restore lake levels and enhance fish habitat. The nineteenth and early twentieth-century logging industry had changed the landscape not only by the extensive logging but also through building a system of dams, weirs, and bridges on the lakes. Here, the question for park managers is one of balancing the interests of restoring a natural ecological system, with preserving the remains of the cultural landscape. Some disturbance to the cultural features will be needed to restore a natural water flow, but it will be minimized, and interpretive trails are planned to showcase the logging features (Fig. 7).

Third Phase, Archaeologists as Regulators

In 2012, Parks Canada began a significant reorganization and downsizing. Regional offices were eliminated as an independent administrative level, although a reduced staff presence is maintained in the regional cities. There were draconian cuts to archaeological staff and facilities, and the cultural services function was centralized in Ottawa. Service centers in the regional offices used to have their own budget envelope to support archaeological work. With this budget gone, most fieldwork has to be fully supported by the individual parks and sites, and the parks of course are juggling many other operational and research priorities. The labs in Vancouver and Victoria were closed, and only two senior archaeologists were left in each of the remaining regions. Conservators and historians remain in the offices outside of Ottawa, but the long-term plan is to centralize all of the repository collections as well as the conservation labs in Ottawa and Gatineau. The closure of regional artefact storage facilities is facing considerable opposition in Dartmouth, where a state-of-the-art conservation lab and storage facility was only opened in 2009. Protests against its

Parks Canada: Historical Archaeology, Fig. 7 Removing a wood sample for dendrochronological dating, from a 19th C dam at the outlet of Lac Dauphinais, La Mauricie NP. (Parks Canada, 1052G, M. Bernier)

closure are coming from professional archaeologists in Atlantic Canada, Indigenous and Acadian groups, and the local Member of Parliament; they protest the waste of closing such a new facility, the loss of artefacts from the territory where they were found, and the difficulties of travelling so far away to access them for study. Concerns about fiduciary responsibility for artefacts in treaty situations have in the past prompted Parks Canada to come to agreements with local repositories; for example, artefacts from excavations in Gwaii Haanas are stored at the Haida Heritage Centre in Skidegate, K̲ay Llnagaay, rather than in Winnipeg with the rest of the artefacts from the west. It may be that similar pressures ensure that some regional artefact collections are maintained closer to where they were found.

This reorganization had a significant effect on the nature of archaeological work undertaken by Parks Canada. Archaeologists currently undertake much less in the way of primary research or field survey and spend much more of their time in a regulatory job. Any large-scale fieldwork is undertaken by archaeological contractors now, and Parks Canada staff are developing processes to administer and review the work of contractors in a manner analogous to the long-established provincial and territorial archaeological regulatory bodies.

Since 2015, the federal government has funded an intensive and wide-scale program of much-needed infrastructure works in the parks system. This has funded repair work at large masonry structures such as the fortifications of Québec, at the masonry and lock structures on the canals of the Trent Severn and Rideau waterways, and at concrete structures such as the military barracks at Fort Rodd Hill NHS. Infrastructure funding is twinning major highways, developing a 270-km-long bicycle trail beside the Icefields Parkway in Banff and Jasper NPs and a bicycle trail along the coast of Pacific Rim NPR. These travel through areas of high site concentration. Infrastructure development on this scale has not been seen since the heady days of historic site reconstruction in the 1960s and 1970s. However, the management response then was to build up a team of archaeologists and historians. Today, it has been a challenge for a much-reduced staff to meaningfully participate in the environmental impact assessment work necessary to respond to massive infrastructure developments in a short time frame. For example, in the western mountain parks, the Trans-Canada highway follows the route of linear sites such as the Kicking Horse Pass NHS in Banff NP and Yoho NP and Rogers Pass NHS in Glacier NP. In both of these cases, from one end of the NHS to the other, the extensive road work is disturbing historical archaeological remains and a cultural landscape related to construction of the Canadian Pacific Railway in the 1880s (Fig. 8). How does a historic archaeologist prioritize the salvage and recording of massive industrial scale features and artefacts, in a constrained mountain pass landscape, where the working season is only a few months long? Archaeological excavation prior to the infrastructure work was not possible. The response has involved coordinating a number of simultaneous contract archaeology projects, developing a site monitoring and accidental finds collection protocol with resource conservation staff from the national park who are continually on the ground, and recording the extant cultural landscape through videos and architectural drawings, with the help of Public Works architectural expertise, before construction alters it.

On the other hand, infrastructure work has sometimes allowed archaeologists to make new discoveries. In 2014 and 2015, a repair of the masonry escarpe walls at the Fortifications of Québec NHS meant that large stretches of the defensive walls were fully exposed (Fig. 9). This presented an opportunity for archaeologists to record in detail the evolution of the wall structures over time, in a sort of dirtless vertical archaeology. The original components of the wall could be linked to documentary evidence and the work of known eighteenth-century military engineers. New discoveries were also made. At the casemate of the Glacière of the Québec citadel, originally built in 1749, stages in the evolution of the structure could be tied to functional changes over time in the defensive features and the barracks. A series of stone survey markers had been built into the wall, and many of these were a style that had not previously been documented. An excavation this extensive for purely research purposes would not have been possible.

Parks Canada: Historical Archaeology, Fig. 8 Foundations of Glacier House, 1886–1925, at the summit of Rogers Pass NHS, within Glacier NP, British Columbia. Glacier House was a Canadian Pacific Railway hotel built at the foot of the Illecillewaet Glacier, to provide facilities for tourists and alpinists in what was at the time considered to be a wilderness. Excavations here uncovered vast quantities of the material culture associated with the transcontinental CPR operation. (Parks Canada, J. Porter, 22 T-11E)

Parks Canada: Historical Archaeology, Fig. 9 A portion of the massive fortifications at the citadel of Québec, exposed during infrastructure repairs in 2016. (Parks Canada, 31G, P. Cloutier)

Similarly, at the Carleton Martello Tower NHS overlooking the harbor in Saint John, New Brunswick, no archaeological work had ever been done before an infrastructure project to stabilize the tower masonry. The stone tower was built during the war of 1812 and went through cycles of military use and abandonment right up through the Second World War. A staging area for the construction project was needed, and in order to clear this and mitigate the impact of any damage from the construction to buried resources, a contract excavation took place at the site of the

adjacent 1826 Signalman's House. This produced structural evidence, as well as an abundance of domestic artefacts illustrating the mid-nineteenth-century occupation.

The distinction between historical and precontact period archaeology is not always clear or even a useful distinction to make. In 2017, a project in the Gulf Islands National Park Reserve, an archipelago on the Pacific coast between Vancouver Island and the mainland, has focused on investigating and restoring a series of clam gardens in the face of a rising sea level. These are Indigenous stone wall features built in the intertidal zone, designed to enhance and enlarge habitat suitable for edible clams by trapping sediment behind them, protecting the beach from being scoured by tides, and creating gently sloping beach sediments on rocky shores where there was no suitable habitat before (Fig. 10). Dates from the barnacle scars on the rocks show the rock walls can date from 2000 years ago, some of them continuously maintained up to historic times (Neudorf et al. 2017). These features have only recently been recognized by coastal archaeologists, but once people started looking for them, they are finding them in many places. The Gulf Islands NPR project is a partnership between Parks Canada archaeologists, parks ecological staff, the Hul'qumi'num and W̱sáneć First Nations, and archaeologists from the Hakai research institute. It is an opportunity for park staff and Indigenous people to learn from each other, for elders to teach youth, and for ecological restoration. Is this historical archaeology? Not in the usual sense, which in Canada has meant the archaeology of the colonial settlers, but it is in the sense that it is the archaeology of the community currently living in the area and their deep history. In this case, as in any other historical archaeology project, archaeological methods provide a way for the current community to learn something about their past ways of life and for the traditional knowledge of the current community to elucidate the meaning of the archaeological remains and features.

Marine Archaeology

Parks Canada has an internationally renowned underwater archaeology unit. Since 1965, marine archaeologists have undertaken a wide range of inventory, CRM, and research projects. Their primary focus is on historic wrecks, but they have also recorded 5000-year-old submerged Indigenous fishing weirs at Atherley Narrows in Mnjikaning Fish Weirs NHS and submerged townsite features in the Lake Minnewanka reservoir in Banff NP. The most extensive excavation began in 1978 at the sixteenth-century Basque whaling settlement at Red Bay NHS, on the

Parks Canada: Historical Archaeology, Fig. 10 Rock wall forming an intertidal clam garden feature, Gulf Islands. (Parks Canada, W. Perry)

south coast of Labrador. After the investigation of four whaling galleons and four smaller whaling craft, the ships were reburied in situ (Grenier et al. 2007). Land excavations at the Red Bay settlement were done by Memorial University. In recent years, the challenging but successful search in high Arctic waters for the *Erebus* and *Terror*, the lost ships of the Franklin expedition, has preoccupied the marine archaeology team and fascinated the nation (Geiger and Mitchell 2015). In the process, they also discovered McClure's *Investigator*, abandoned in 1853 during the search for Franklin. Parks marine archaeologists used their considerable research and technical skills and the ever more powerful abilities of remote sensing technology, but the project succeeded because of the contributions of land archaeologists from the Northwest Territories, Inuit who brought their local knowledge, and a partnership with the Royal Canadian Geographical Society and the Canadian Navy. Beginning in 2017, Inuit guardians will be camping near the site of the *Erebus* during the season it is accessible, to keep an eye on the site and to provide interpretation to visitors. This is analogous to the established Haida watchman program, where members of the Haida nation camp at the isolated Ninstints NHS in Gwaii Haanas NPR for the same purposes. Both are isolated sites, and the cultural knowledge of the watchmen adds a vital dimension to the experience of a visitor. In a way, this is a return to the "living history" site concept that was promoted at the very beginning of the Parks Canada archaeology program.

Future Directions for Historical Archaeology

Parks Canada archaeologists are still refining their role as a regulatory body. The federal infrastructure funding will continue for a few years, necessitating a high number of archaeological projects as part of the environmental impact assessment and mitigation process. The procedures for permitting, supervising, and reviewing the work of contracting archaeologists, and integrating the results into the Parks Canada site and collections databases, have been worked out on the fly during this extremely busy time. Contractors are used to following the regulations of the various provinces and territories, which differ in some important regard from the processes used by Parks Canada archaeologists. Although the sheer volume of work will diminish as the infrastructure program winds up, there are so few Parks Canada staff archaeologists that contracting archaeologists, or academic partners, will still be needed to carry out any substantial archaeological field project. Some of these partnerships have been extremely fruitful. In the past, however, some academic researchers have been reluctant to comply with Parks Canada permitting and reporting processes, and oversight would be required with any research partner.

In the longer term, Parks Canada archaeologists will continue to carry out smaller-scale field projects, provide advice to the operational managers and interpreters at the individual parks and sites, and participate in environmental assessment reviews. They will continue to provide advice and research as needed for the work of the HSMBC: contributing to background papers and community consultations for new site nominations and contributing to preparation of the Commemorative Integrity Statements that guide the management and interpretation. They will continue to participate in the site inventory needed for new park and site establishment.

Parks Canada archaeologists will be working with Indigenous communities. A collaborative relationship is well established in the new northern parks that came into the system as part of the modern treaty process and the park reserves on the Pacific coast, established in a province where treaties have not yet been signed. In these cases, park management is often explicitly a co-management or consensus process, and archaeologists do their fieldwork along with Indigenous colleagues from the park staff or knowledgeable community members. In Gwaii Haanas NPR, where the park has been cooperatively managed right from its inception, the information that archaeology can contribute is seen by the Haida as making important parts of their culture and history visible to the Haida and their youth and to the world. In 2013, a new totem

pole was raised at Windy Bay in Gwaii Haanas NPR, to honor the agreement between the Haida and Parks Canada and to tell the story of the park. Jaalen Edenshaw, Tyler York, and Gwaii Edenshaw carved the Legacy Pole, the first to be erected here in 130 years, and included figures in the pole design explicitly recognizing archaeological findings and an archaeologist.

In the southern parks and sites, this level of collaboration is not yet well established, but it is a goal. For example, research and management issues in the new Rouge National Urban Park are considered by an Indigenous advisory circle, with representatives from ten First Nations with interests in the park area. Members from these communities monitor and review archaeological projects, whether they concern historical or precontact archaeology, and may choose to participate more fully in the actual fieldwork. The Rocky Mountain national parks, parks that were established long ago in areas where there already were treaties, have less formally structured relationships with the surrounding communities. Relationships are well established for some management and resource access purposes, but the communities may not always consider archaeological matters as the most important aspect of their relationship with the park. However, it is becoming increasingly common to alert the First Nations of pending projects and provide the opportunity for comment or participation, in the same way that consulting archaeologists are required to do in many provinces and territories.

Another kind of archaeological research that is becoming important is developing formal monitoring protocols and techniques at threatened sites. Whether sites have historic or precontact structures and features, they are being damaged by erosion, weather, and neglect. Archaeologists are beginning to work with park operational staff to define monitoring procedures that non-archaeological staff can use. This involves such new and noninvasive technology as drone overflights, side-scan sonar, or digitally stitching together photographs to produce a 3D version of an eroding riverbank. Staff have developed expertise in using noninvasive geophysical survey methods such as ground-penetrating radar, so that an area can be surveyed without actually digging and disturbing the resources and any excavation work can be most efficiently targeted. A still expensive technique is a complete 3D laser scan of the structures at a site, which produces a highly detailed volumetric record of the entire site, but this will surely come down in price as technology develops.

The public dissemination of research results continues to be a challenge. Archaeologists produce excellent and detailed reports on their work, but as is the case with many government documents, it is gray literature. Formal publication in Canada of a government document requires translation and publication in both French and English. In the early days, Parks Canada published a series of monographs for external use on the architectural history and built heritage of the NHS reconstruction projects, called Studies in Archaeology, Architecture, and History. This included monographs on a particular material culture, such as a classification of historic trade beads that remains a standard reference (Karklins 1985). Many research reports were internally published in a Manuscript Report Series, in the language of their author, which later became the Microfiche Report Series. Short project summaries were externally published in the Research Bulletin series. Both of these series were discontinued in the early 1990s, and the dedicated editorial unit in Parks Canada disbanded. For several years in the mid-1990s, the Western Region published a Research Updates bulletin for external distribution. Libraries in the regional offices were disbanded in 2012, and external researchers now must work through the central Parks Canada library to obtain access. Archaeologists continue to publish their results in professional conferences and journals, but the majority of their research and project results are produced in internally distributed reports and remain in the gray literature.

Another opportunity to disseminate archaeological research is provided by staff training. Each year, archaeologists and historians participate in the seasonal interpretive staff training and prepare background resources so that interpreters base their programs consistently on the most up to date and accurate research. Winnipeg historians

have for a long time prepared an online resource package that includes archaeological and historical research papers, images, and key archival documents for each of the operating NHS in their region. Archaeologists present talks at the summer campground lecture series and participate in "antique road shows." For many years Banff NP has run a lecture series, to update the town on the full range of natural and cultural research projects taking place in Banff. These are great fun to be a part of, and the archaeologists always learn something too from the well-informed and well-travelled audiences.

What will surely continue into the future, what attracts archaeologists to work with Parks Canada, is the sense that no matter what the challenges and frustrations are, archaeologists know they are making a contribution to the understanding and preservation of significant archaeological sites and protected heritage areas. They are working as part of a team of colleagues from many disciplines, toward the same admirable long-term goals, spelled out in the mandate of Parks Canada: to protect and present nationally significant examples of Canada's natural and cultural heritage and foster public understanding, appreciation, and enjoyment in ways that ensure ecological and commemorative integrity of these place, for present and future generations.

Parthenon (Elgin) Marbles: Case Study

Eleni Stefanou
Management of Cultural Organizations,
Hellenic Open University, Athens, Greece

State of Knowledge and Current Debates

Introduction

The Parthenon (Elgin) Marbles are a group of marble sculptures from the Athenian Acropolis owned since 1816 by the British Museum. They have gained twofold significance, as pieces that encompass the glory of Classical Greece and as perhaps the most famous case related to the issue of repatriation of material culture up to now. For more than 200 years, they have been appropriated as signifiers of identity by Britain and Greece and have been one of the most pervasive national claims by the Greek governments, setting the scene for Greek cultural diplomacy, especially after the inauguration of the New Acropolis Museum in June 2009.

Definition

The "Elgin Marbles," as the British Museum is obliged by statute to refer to this group of artefacts since their acquisition in 1816 (Hitchens et al. 1997, pp. viii, 17, 43), or the "Parthenon Marbles" as the Greek official national rhetoric addresses them (Yalouri 2001, pp. 97–98), is a group of marble sculptures, statues, inscriptions, and architectural members that, between 1801 and 1802, were removed from the Athenian Acropolis, at the time under Ottoman occupation, by the Seventh Earl of Elgin, Thomas Bruce (Greenfield 1996, p. 330; Hitchens et al. 1997; Hamilakis 2007).

The most renowned group of these artefacts is the ensemble of the marble sculptures which belonged to the fifth-century BC Parthenon Temple that depict mostly scenes from the Greek mythology. Almost half of its sculptures are currently displayed in the British Museum and the other half in New Acropolis Museum of Athens. In addition, fragments from the Parthenon sculptures can be found also in other museums, in France, Denmark, Germany, Austria, France, and Italy (Greenfield 1996). The monument's fragmentation has been the issue of intense ongoing debates, and the Parthenon (Elgin) Marbles are firmly entangled with the demand of the repatriation of cultural heritage.

Key Issues/Current Debates

Repatriation of cultural heritage is not an easy to tackle issue, as it is connected to the question "who owns cultural heritage?" Is it the nation and its subjects? Is it individual collectors? Is it local communities? Museums? Humanity at large? Or is it about a monument's integrity and intactness? The answer is rather complicated, especially because in the case of the Parthenon

(Elgin) Marbles the international conventions for the protection of cultural heritage (The Hague Convention of 1954, the UNESCO Convention of 1970, and the UNIDROIT Convention of 1995) do not apply, as the Parthenon (Elgin) Marbles were acquired before the conventions' inception. Therefore, it is necessary to look into the historical dimensions of the debate, especially the context of the Marbles' removal from the Athenian Parthenon in the era of British colonialism, and reflect on the history of collecting which formed the modus operandi of many contemporary world museums (Curtis 2006, p. 118).

Classical art offered to the British Empire a sense of rebranding through culture (Rose-Greenland 2013) because the aesthetic values through which it was viewed were thought to signify harmony, morality, and excellence, virtues that perfectly suited upper-class Britain. Thomas Bruce, as the British Ambassador to the Ottoman Empire (1799–1803), benefitted from the auspicious British-Ottoman political relationships that were developed during the French-Turkish War, when Britain became an ally of the Ottoman Empire rivaling France on a political, military, and cultural level (Greenfield 1996, p. 335). The acquisition of the Elgin marbles, with a controversial permit obtained from the Ottoman administration, was for the British a matter of power and authority vested with cultural connotations. British imperialism was thus ascertained through the projection of Britain as the successor of classical Athens that managed to rescue the classical material culture from destruction (Greenfield 1996, p. 337).

The fact that a foreign culture was being appropriated by the British imperialist narrative did not seem to be at odds with the national and supranational sentiments at the time (Rose-Greenland 2013). That is exactly because the Parthenon (Elgin) Marbles were deemed as pre-national, having been created prior to nation-states by a culture with a sociopolitical formation different to that of the nation (Rose-Greenland 2013). Hence, the Parthenon (Elgin) Marbles were considered cultural products of a long-lost civilization, the remnants of which were only ruins found in the then Ottoman-occupied Athens. This ambiguous state of being enabled them to acquire a dual subsistence by belonging to no one in particular and simultaneously to everyone.

This universalist approach is in absolute synch with the concept of the *universal museum*, that is, the *encyclopedic museum*, which presents itself as a representative of the whole humanity (Cuno 2006, 2011). Encyclopedic museums, the British Museum among them, are thought to promote diversity of world cultures and the "spectacular" art that is mankind's common heritage. As stated in the website of the British Museum: "the Museum is a unique resource for the world: the breadth and depth of its collection allows a world-wide public to re-examine cultural identities and explore the complex network of interconnected human cultures. The Parthenon Sculptures are a vital element in this interconnected world collection. They are a part of the world's shared heritage and transcend political boundaries" (The British Museum n.d.).

Supranational narratives are the core of the encyclopedic museums, which are rendered world museums. Regarding the Parthenon (Elgin) Marbles, the British Museum shapes its argument by drawing on the fact that their fragments exist divided in museums of eight countries in total (Hitchens et al. 1997, pp. 109–115; Hamilakis 2007; Rose-Greenland 2013), which supposedly enables different stories to be told. This argument reproduces the nineteenth-century British narrative and colonial ideas about the universalism of culture, while it adeptly overcomes the issue of the monument's fragmentation. Nonetheless, the Marbles also elevate the position of the British Museum as a world museum, where high art can be admired by visitors from all over the world, art with no nationality but with supranational world significance.

That is precisely the argument employed against the Greek state's claims for the repatriation of the Parthenon (Elgin) Marbles, as the term "world heritage" is supposed to overrule any Greek claims of ownership and repatriation, thus validating the Parthenon (Elgin) Marbles retention in the British Museum (Simpson 2005, pp. 253–254).

Yet, Greek's claims for the repatriation of the Parthenon (Elgin) Marbles were expressed

right after the formation of the independent Greek nation-state, in 1830, striving to confirm homogeneity and continuity between ancient and modern Greece. In this process, classical antiquities acquired nationality and were the driving force toward the construction of a coherent national identity. The assertion of direct lineage with classical Greece allowed Greek governments to demand the exclusive ownership of antiquities, the materiality of which provided the newly founded nation-state with strong visual images, recognizable among the European elites.

The repatriation of the Parthenon (Elgin) Marbles was officially placed for the first time as a political and diplomatic demand in 1982 by the then Greek minister of culture, Mrs. Melina Mercouri, at the World Conference on Cultural Policies (Mexico City, 29 July 1982) organized by UNESCO (http://melinamercourifoundation.com/unesco%CE%BC%CE%B5%CE%BE%CE%B9%CE%BA%CF%8C-29-7-1982/). She stated in her speech: "You must understand what the Parthenon Marbles mean to us. They are our pride. They are our sacrifices. They are our noblest symbol of excellence. They are a tribute to the democratic philosophy. They are our aspirations and our name. They are the essence of Greekness" (http://melinamercourifoundation.com/en/oxford-union-june-12-1986/).

Eventually, the Acropolis was inscribed on the world heritage list in 1987, described as "Illustrating the civilizations, myths and religions that flourished in Greece over a period of more than 1,000 years, the Acropolis, the site of four of the greatest masterpieces of classical Greek art — the Parthenon, the Propylaea, the Erechtheum and the Temple of Athena Nike — can be seen as symbolizing the idea of world heritage" (UNESCO 1988).

Over the years, the demand for the Marbles' repatriation resurged in various occasions, such as the 2004 Olympic Games which were hosted in Greece and the inauguration of the New Acropolis Museum in 2009. As Plantzos notes (2009, p. 14), "the majority of the Greek Press, part of the international Press, as well as the public seem to support that the New Acropolis Museum [. . .] can act as a lever for new claims of national importance, as it has a clear political dimension." Thus, in 2012, the Ministry of Culture and Tourism established an Advisory Committee in order to proceed with a planning strategy toward the return of the Parthenon Marbles and the fulfillment of this national goal (Greek Ministry of Culture n.d., 19/09/2012).

Apart from the claims of ownership, another powerful argument is the unification of the monument itself, the cultural biography of which continues being fragmented. The fact that the Parthenon (Elgin) Marbles, if ever returned to Greece, will be put on display in the New Acropolis Museum and not on the Parthenon itself does not weaken the sense of the monument's reunification, as the visual contact and proximity of the sculptures to the monument would create a materially contingent ensemble. This desire for reunification is clearly expressed within the New Acropolis Museum, where the demand for the repatriation of the Parthenon (Elgin) Marbles is transformed into a physical experience, as the visitor is called to engage with the notion of void and absence. Empty spaces are left to indicate the missing pieces, most of which are displayed in the Duveen Gallery of the British Museum.

On Absence

The New Acropolis Museum has, by definition and by intention, been identified with the negotiation of absence (Beresford 2016; Bounia 2012; Lending 2009; Plantzos 2009, 2011a, b, c; Hamilakis 1999, 2011), as, according to Plantzos (2009, p. 14), "the building seems to have been made to house some of the absent exhibits rather than the existing ones." From an ontological point of view, absence and the understanding of it is a complex phenomenon that causes emotions such as embarrassment and anxiety, which is why it raises a variety of human reactions (Anagnostopoulos 2014, p. 64), something that is also evident in the rhetoric which surrounds the New Acropolis Museum. Negotiation of absence here is twofold: on the one hand, absence is regarded not just as merely an abstract concept inherent in archaeological practice but as a factual situation associated with the absent Parthenon (Elgin) Marbles. As stated by Mr. Pantermalis, the director of the New Acropolis

Museum, in 2007 "The Museum clearly presents the problem of the Parthenon Marbles. There is no need to say anything, it is clear, and the public will understand it" (Leoudaki 2007). On the other hand, absence is experienced on a symbolic level as part of the missing national soul. As stated by Mr. Antonis Samaras, minister of culture, during the opening of the New Acropolis Museum in 2009, "What you will see [in the New Acropolis Museum] are not just a part of our history. They are part of ourselves. [. . .] And more of a part of our soul, are those that are missing" (Chouzouri 2014).

Absence, then, is rendered a physical experience, as the visitor is called to negotiate actively with void space. The presence of absence and its constant reminder create and communicate the feeling of an indefinable nostalgia "for the whole" (Hamilakis 2012), for something that is considered as granted even if it is not associated with direct, primary memories of modern subjects. Through this interplay of presence and absence, the New Acropolis Museum successfully manages to display a collection which it does not possess (Lending 2009, p. 572). It, thus, states at the level of international relations and cultural diplomacy not only the resilience of the demands for the return of the Parthenon (Elgin) Marbles but also specific political realities, such as the competing nationalisms involved in claiming the Parthenon (Elgin) Marbles; the interplay between imperial, colonial, and national practices; and the interplay of the local and the global in the field of cultural economy (Hamilakis 2012, p. 274).

On Trauma

In this light, absence has to do with loss, with the cessation of "having," with death, drama, and deprivation, and is, therefore, directly related to the concept of trauma. Thus, absence is not just spatially denoted inside the museum but also discursively constructed:

> As the then prime minister of Greece stated during the New Acropolis Museum's inauguration in June 2009 "The new museum is not a museum of deprivation, but a top museum despite the wounds" (http://www.minpress.gr/minpress/index/information/acropolis_inauguration.htm). In a similar spirit, the president of the Democracy at the time, Mr. Karolos Papoulias, supported that "It is time to heal the wounds of the monument by returning the marbles that belong to them" (http://www.minpress.gr/minpress/index/information/acropolis_inauguration.htm). Likewise, as stated in the Greek press around the time of the New Acropolis Museum's inauguration, "The tour in the exhibition hall of the Parthenon Marbles is [. . .] a cry for the fragmented sculptures. On the ancient marbles, the wounds from Elgin's tools are still visible" (Eleftheros Tyops tis Kyriakis, 21/7/2009, p. 39/7).

The aforementioned statements are only a few, indicative of the dozens of articles published in the national and international press, which render the Acropolis apart from a key monument of Western civilization a wounded monument (Liakos 2011). Accordingly, the New Acropolis Museum becomes internationally the guardian of this open trauma, which does not heal until the Parthenon (Elgin) Marbles are returned, essentially becoming a metonym of trauma through loss (Liakos 2011). Trauma, in the case of the Parthenon (Elgin) Marbles, is twofold: on the one hand, it is a national, historical, cultural, and collective trauma expressed through the loss of the Parthenon (Elgin) Marbles and, on the other hand, it is a kind of an embodied and experienced trauma, as the Marbles acquire human qualities and appear to speak, scream, hurt, and demand (Hamilakis 2012; Stefanou 2014).

The national cultural trauma is linked to a historical event fundamental to national culture and collective identity (Yair and Odom-Weiss 2014, p. 3), that of the removal of the Parthenon Marbles by Lord Elgin. Despite the distance from the event itself and the absence of lived memories, trauma appears as an integral part of a felt experience that reflects the social construction and ideology of the dominant culture (Gurevich 2016, p. 6). The traumatic event is recorded in the collective subconscious through the creation of national narratives and performative acts (Alexander 2012), prompted not only by the institutional administrators of memory but also by citizens' movements, individuals, etc. Thus, trauma cannot be forgotten as its emotional weight is not removed but is constantly emphasized through absence, whether it is in the permanent exhibition of the museum, the rearticulating of the repatriation demands, or through the media

discourses. Thus, the notion of trauma is very powerful precisely because it is a constantly experienced situation. De-traumatization cannot occur nor can reconciliation be realized until the demands of the Greek state have been satisfied.

In the case of the embodied trauma, museum exhibits are attributed human feelings and qualities such as pain, sadness, nostalgia, disappointment, longing, deprivation, physical pain, speech, voice, etc. Hence, objects are perceived as living organisms, as soulful beings who speak the same language as the visitors and feel the same feelings with them. The dialectical relationship that develops between the objects and the public is mediated through the notion of trauma and the process of victimization, as the exhibits appear to be carrying wounds, to be broken and dismembered, alone, and imprisoned in the British Museum, a status that preserves difficult-to-manage feelings and charges the inter-historical communication of the public with the past (Stefanou 2011). As Plantzos points out (2011a, p. 27), it is through this process that the objects undertake independent action and acquire agency, speaking to the public as autonomous subjects and not as museum exhibits that mediate messages and symbolisms.

Invoking the traumatic works successfully because of its directness and immediacy to touch universal human values such as mourning and death, loss and pain, freedom, and the need for vindication, which when it comes it will mark the reconciliation with historical trauma as well as the fruitful transnational co-operation.

On Kinship

The Parthenon (Elgin) Marbles are often thought as the next of kin. As a young visitor of the New Acropolis Museum stated: "I miss them. It is as if they took away my family. They may not want to give them back to us, but we will insist, and we will succeed" (http://www.ethnos.gr/politismos/arthro/ta_marmara_kaloun_ta_marmara-4236889/). Likewise, on the national press after the New Acropolis Museum's inauguration, it was stated that "The five stars of the Museum [...] wait for their sixth sister from London" (Eleftheros Typos tis Kyriakis, 21 Ιουλίου 2009, p. 10/82). In the same vein, the south African Nobel Prize winner writer, Nadine Gordimer, stated that "The Parthenon Marbles are part of the artistic DNA of the Greeks and they belong there" (http://www.parthenonuk.com/bcrpm-latest-news/300-remembering-nadine-gordimer-supporter-for-the-reunification-of-the-parthenon-marbles).

These statements are only three among the many expressed during the New Acropolis Museum's inauguration. They are indicative of the way in which material culture is understood through the lens of both biological and cultural determinism in discourses about the Parthenon (Elgin) Marbles and the role of the New Acropolis Museum (Stefanou 2011) in keeping "our" relatives safe. In this context, the concept of direct affinity with classical civilization is thought to be one of the basic components of modern Greek national identity. Affinity, here, is not just expressed by the public, i.e., the people of Greece, the museum's visitors, the supporters of the Parthenon (Elgin) Marbles' return, etc., but it also appears to be invoked by the material culture and by the museum exhibits themselves, which, as already mentioned, acquire a soul and now also function themselves as subjects, having acquired agency.

It is almost an animist approach through which material objects acquire social identities and develop social relationships with the people that surround them (Sillar 2009, p. 369). They are considered part of an extended family, that of the nation-state, and these ties act as catalysts in stimulating national imagination regarding kinship, blood, DNA, and, hence, indissoluble national continuity. As Sillar (2009, p. 28) points out, material culture can raise a variety of human reactions, but the extent to which objects are perceived as carriers of agency derives from how the subjects themselves, humans, consciously make meaning of the material culture. In the case of the Parthenon (Elgin) Marbles, the meaning-making process takes place in the framework of kinship and family ties.

Although family functions as a cultural metaphor here, family ties are considered as de facto unbreakable, and therefore, at a level of cultural

diplomacy, they can form an argument that may be stronger than the traditional approaches to national identity. Given that the members of a functioning family protect one another and pursue its prosperity, the argument of family ties is the culmination of the hitherto established historical-political perceptions of identity, with the New Acropolis Museum being the family home.

The ancestral and fraternal relationship that develops between modern citizens and the material culture of the classical past strengthens the validity of the demands for the return of the Parthenon (Elgin) Marbles, wherever they derive from. At the same time, this rhetoric emphasizes on the ecumenical dimension of the Greek classical culture, the New Acropolis Museum, the Parthenon (Elgin) Marbles, and the Greek nation itself, for family here is perceived as a supranational guardian of universal values all encompassed in the New Acropolis Museum.

On Debt

The universal values and family ties promoted by the New Acropolis Museum through the Parthenon (Elgin) Marbles are directly linked to the concept of debt, which here acquires a dual content: on the one hand, it is linked to the cultural and moral debt of the West toward modern Greece and, on the other hand, to the economic crisis and financial debt of the Greek state. As Hamilakis (2016, pp. 27–28) states, the debt to ancient ancestors is juxtaposed with the modern financial debt and the Greek financial crisis provides a platform for various actions with archaeological-political content. In this case, the Parthenon (Elgin) Marbles are a symbol of pillage, not only of the one that Greece and its antiquities suffered by the Europeans in the nineteenth century but also of the pillaging that is currently undergoing amidst the economic crisis, privatization, unemployment, etc.

This belief is clearly expressed through various protest events organized in relation to the Parthenon (Elgin) Marbles: in 2015, the international campaign against debt, the *Jubilee Debt Campaign*, in collaboration with the international organization for social justice, *Global Justice now*, organized a protest of solidarity at the Duveen Hall of the British Museum, where the Parthenon (Elgin) Marbles are housed (http://www.globaljustice.org.uk/news/2015/jul/3/elgin-marbles-targeted-greek-solidarity-protest-british-museum and http://www.economicvoice.com/elgin-marbles-targeted-in-greek-solidarity-protest-in-british-museum/). They raised a banner that read *OXI No – No More Looting – Support Greece*, obviously referring to the imminent referendum of the 5th day of July 2015, but also linking their protest with the Parthenon (Elgin) Marbles both spatially and verbally by using the word looting.

A member of the Jubilee Debt Campaign, Mr. Stevenson, who was present in the protest, stated that "the Parthenon Marbles are the international symbol of the Greek pillage. We are here today to say not to the modern despair of the Greek state through the imperative austerity [. . .]. Just as with marbles, the modern looters primarily serve their own interests while claiming that they do it for the good of Greece." Earlier this year, on the 25th day of April, a team of Greek archaeologists and students along with members of the *Coalition of Resistance* and the *Greek Solidarity Campaign* organized a protest in the same hall of the British Museum with a banner that stated "Cannot pay. Will not pay. Solidarity with Greece" (http://www.keeptalkinggreece.com/2012/04/25/solidarity-with-greece-protest-inside-the-british-museum/).
